

## Properties of proof systems

- Important properties of a proof system:
  - Soundness: if  $U \vdash V$  then  $U \models V$  (what we prove is true)
  - Completeness: if  $U \models V$  then  $U \vdash V$  (what is true can be proven)
- Gödel's completeness theorem (1929) states that a proof system for FOL using modus ponens is complete (and sound, of course)
- This can be reformulated as:  
the two kinds of consequence – semantic and syntactic – are the same

$$\models \equiv \vdash$$

see the logo of the Association for Logic Programming (ALP):

Association for Logic Programming

## Issues with FOL: it is not powerful enough

- FOL is **not powerful enough**, as it is not possible to uniquely describe arithmetic on natural numbers using FOL
- The set of natural numbers has the following property:

*Every integer can be obtained from 0 by adding 1 a finite number number of times* (\*)

- Property (\*) cannot be transformed to a FOL formula, and therefore FOL axiomatisations of arithmetic (e.g. by Peano) have so called non-standard models: in these models there are integers that cannot be reached from 0 by a finite number of incrementation steps
- Gödel's **incompleteness** theorem states that there is an arithmetic formula  $\varphi$  that is true in the **(single)** model of natural numbers but cannot be proven (equivalent to stating "I am not provable")
- This is not contradicting Gödel's **completeness** theorem, as there is a non-standard model in which formula  $\varphi$  does not hold

## Issues with FOL: it is too powerful

- FOL is **too powerful**, as it is not (fully) decidable
- A logic is (fully) decidable if there is an algorithm which, given the question if  $S \vdash \alpha$  is guaranteed to terminate with a yes or no answer
- FOL is semi-decidable: there is an algorithm (e.g. FOL resolution) that is guaranteed to terminate if  $S \vdash \alpha$  holds, but may not terminate if  $S \vdash \alpha$  does not hold
- In the past  $\sim 30$  years some subsets of FOL, called **Description Logics**, have been identified and shown to be (fully) decidable: for these sublanguages there are algorithms that return a yes/no answer to the question:  $S \vdash \alpha$ ?
- We will learn about Description Logics, used mostly in the Semantic Web, in the final part of the course

## Prolog in the family of programming languages

## Prolog

- Birth date: 1972, designed by Alain Colmerauer, Robert Kowalski
- First public implementation (Marseille Prolog): 1973, interpreter in Fortran, A. Colmerauer, Ph. Roussel
- Second implementation (Hungarian Prolog): 1975, interpreter in CDL, Péter Szeredi  
<http://dtai.cs.kuleuven.be/projects/ALP/newsletter/nov04/nav/articles/szeredi/szeredi.html>
- First compiler (Edinburgh Prolog, DEC-10 Prolog): 1977, David H. D. Warren (current syntax introduced)
- Wiki: <https://en.wikipedia.org/wiki/Prolog>

## Prolog – PROGRAMMING in LOGIC: standard (Edinburgh) syntax

| Standard syntax                | English                                 | Marseille syntax               |
|--------------------------------|---|--------------------------------|
| <code>has_p(b, c).</code>      | <code>% b has a parent c.</code>        | <code>+has_p(b, c).</code>     |
| <code>has_p(b, d).</code>      | <code>% b has a parent d.</code>        | <code>+has_p(b, d).</code>     |
| <code>has_p(d, e).</code>      | <code>% d has a parent e.</code>        | <code>+has_p(d, e).</code>     |
| <code>has_p(d, f).</code>      | <code>% d has a parent f.</code>        | <code>+has_p(d, f).</code>     |
|                                | <code>% for all GC, GP, P holds</code>  |                                |
| <code>has_gp(GC, GP) :-</code> | <code>% GC has grandparent GP if</code> | <code>+has_gp(*GC, *GP)</code> |
| <code>  has_p(GC, P),</code>   | <code>% GC has parent P and</code>      | <code>-has_p(*GC,*P)</code>    |
| <code>  has_p(P, GP).</code>   | <code>% P has parent GP.</code>         | <code>-has_p(*P,*GP).</code>   |

FOL:  $\forall GC, GP. (has\_gp(GC, GP) \leftarrow \exists P. (has\_p(GC, P) \wedge has\_p(P, GP)))$

- Program execution is SLD resolution, which can also be viewed as pattern-based procedure invocation with backtracking
- Dual semantics: **declarative** and **procedural**
  - Slogan: **WHAT** rather than **HOW**  
(focus on the **logic** first, but then think over Prolog **execution**, too).

## Prolog clauses and predicates - some terminology

- A Prolog program is a sequence of *clauses*
- A clause represents a statement, it can be
  - a *fact*, of the form '*head*.' , e.g. `has_parent(a,b)`.
  - a *rule*, of the form '*head* :- *body*.' ,  
e.g. `has_gp(GC, GP) :- has_p(GC, P), has_p(P, GP).` (\*)
- Read ':-' as 'if', ',' as 'and'
- A *fact* can be viewed as having an empty body, or the body `true`
- A *body* is comma-separated list of *goals*, also named *calls*
- A *head* as well as a *goal* has the form *name(argument,...)*, or just *name*
- A functor of a *head* or a *goal* (or a term, in general) is *F/N*, where *F* is the name of the term and *N* is the number of args (also called *arity*).  
Example: the functor of the head of (\*) is `has_gp/2`
- The functor of a clause is the functor of its head.
- The collection of clauses with the same functor is called a *predicate* or *procedure*
- Clauses of a predicate should be contiguous (you get a warning, if not)

## And what happened to the *function symbols* of FOL?

- Recall: In FOL, atomic predicates have arguments that are terms, built from variables using **function symbols**, e.g. `lseq(plus(X, 2), times(Y, Z))`
- In maths this is normally written in *infix operator* notation as  $X + 2 \leq Y \cdot Z$
- In Prolog, graphic characters (and sequences of such) can be used for both relation and function names: `=(< +(X,2), *(Y,Z) )` (1)
- As a “syntactic sweetener”, Prolog supports operator notation in user interaction, i.e. (1) is normally input and displayed as `X+2 =< Y*Z`. However, (1) is the internal, *canonical* format
- The built-in predicate (BIP) `write/1` displays its arg. using operators, while `write_canonical/1` shows the canonical form
 

```
| ?- write(1 - 2 =< 3*4).           => 1-2=<3*4
| ?- write_canonical(1 - 2 =< 3*4). => =<(-(1,2),*(3,4))
```
- Notice that the predicate arguments are not evaluated, function names act as **data constructors** (e.g. the op. - is used **not** only for subtraction)
- Prolog is a symbolic language, e.g. symbolic derivation is easy
- However, doing arithmetic requires special built-in predicates

## Prolog built-in predicates (BIPs) for unification and arithmetic

- Unification.** `X = Y`: unifies `x` and `y`. Examples:
 

```
| ?- X = 1-2, Z = X*X.           => X = 1-2, Z = (1-2)*(1-2)
| ?- U = X/Y, c(X,b)=c(a,Y).    => U = a/b, X = a, Y = b
| ?- 1-2*3 = X*Y.               => no (unification unsuccessful)
```
  - Arithmetic evaluation.** `X is A`: `A` is evaluated, the result is unified with `x`. `A` must be a **ground** arithmetic expression (**ground**: no free vars inside)
 

```
| ?- X = 2, Y is X*X+2.         => X = 2, Y = 6 ?
| ?- X = 2, 7 is X*X+2.         => no
| ?- X = 6, 7-1 is X.           => no
| ?- X is f(1,2).               => 'Type Error'
```
  - Arithmetic comparison.** `A == B`: `A` and `B` are evaluated to numbers. Succeeds iff the two numbers are equal. (Both `A` and `B` have to be ground arithmetic expressions.)
 

```
| ?- X = 6, 7-1 == X.           => X = 6
| ?- X = 6, X*X == (X+3)*(X-2). => X = 6
| ?- X = 6, X+3 == 2*(X-2).     => no
| ?- X = 6, X+3 == 2*(Y-2).     => 'Instantiation Error'
```
- Further BIPs: `A < B`, `A > B`, `A == B` (`<=`), `A >= B` (`>=`), `A \= B` (`≠`),

## An example: cryptarithmic puzzle

- Consider this cryptarithmic puzzle: `AD*AD = DAY`. Here each letter stands for a *different* digit, initial digits cannot be zeros. Find values for the digits `A`, `D`, `Y`, so that the equation holds.
- We'll use a library predicate `between/3` from library `between`.
 

```
% between(+N, +M, ?X): X is an integer such that N =< X =< M,
%                               Enumerates all such X values.
```
- I/O mode notation for pred. arguments (used **only** in comments):
  - `+`: input (bound), `-`: output (unbound var.), `?`: arbitrary.
- To load a library: (in SICStus) include the line below in your program:
 

```
:- use_module(library(between)).
```

In SWI Prolog the predicate is loaded automatically.
- The Prolog predicate for solving the `AD*AD = DAY` puzzle:
 

```
ad_day(AD, DAY) :-
    between(1, 9, A), between(1, 9, D), between(0, 9, Y),
    A \= D, A \= Y, D \= Y,
    DAY is D*100+A*10+Y, AD is A*10+D,
    AD * AD == DAY.
```
- Solve this puzzle yourself: `GO+TO=OUT`

## Data structures in Prolog

Prolog is a dynamically typed language, i.e. vars can take arbitrary values. Prolog data structures correspond to **FOL terms**. A Prolog term can be:

- var (variable)**, e.g. `X`, `Sum`, `_a`, `_`; the last two are *void* (don't care) vars (If a var occurs **once** in a clause, prefix it with `_`, or get a **WARNING!!!** Multiple occurrences of a single `_` symbol denote different vars.)
  - constant (0 argument function symbol)**:
    - number** (*integer* or *float*), e.g. `3`, `-5`, `3.1415`
    - atom** (symbolic constant, cf. enum type), e.g. `a`, `susan`, `=<`, `'John'`
  - compound**, also called **record**, **structure** (*n*-arg. function symbol,  $n > 0$ )
- A compound takes the form: `name(arg1, ..., argn)`, where
- `name` is an atom, `argi` are arbitrary Prolog terms
  - e.g. `employee(name('John', 'Smith'), birthd(20, 11, 1994), 'Sales')`
  - Compounds can be viewed as trees

## Variables in Prolog: the logic variable

- A variable cannot be assigned (unified with) two distinct ground values:
 

```
| ?- X = 1, X = 2.           => no
```
- Two variables may be unified and then assigned a (common) value:
 

```
| ?- X = Y, X = 2.         => X = 2, Y = 2 ?
```
- The above apply to a single branch of execution. If we backtrack over a branch on which the variable was assigned, the assignment is undone, and on a new branch another assignment can be made:
 

```
has_p(b, c).      has_p(b, d).      has_p(d, e).
| ?- has_p(b, Y).           => Y = c ? ; Y = d ? ; no
```
- A logic variable is a “first class citizen” data structure, it can appear inside compound terms:
 

```
| ?- Emp = employee(Name,Birth,Dept), Dept = 'Sales',
      Name = name(First,Last), First = 'John'.
      => Emp = employee(name('John',Last),Birth,'Sales') ?
```
- The `Emp` data structure represents an arbitrary employee with given name John who works in the `Sales` department

## The logic variable (cont'd)

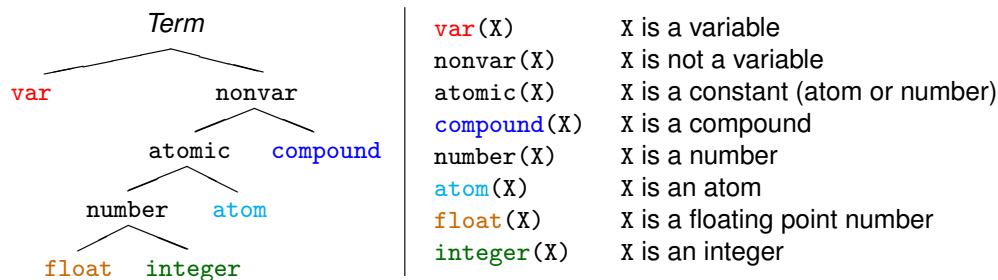

- A variable may also appear several times in a compound, e.g. `name(X,X)` is a Prolog term, which will match the first argument of the `employee/3` record, iff the person’s first and last names are the same:
 

```
employee(1, employee(name('John','John'),birthd(2000,12,21),'Sales')).
employee(2, employee(name('Ann','Kovach'),birthd(1988,8,18),'HR')).
employee(3, employee(name('Peter','Peter'),birthd(1970,2,12),'HR')).

| ?- employee(Num, Emp), Emp = employee(name(_X,_X),_,_).
Num = 1, Emp = employee(name('John','John'),birthd(2000,12,21),'Sales') ? ;
Num = 3, Emp = employee(name('Peter','Peter'),birthd(1970,2,12),'HR') ? ; no
```
- If a variable name starts with an underline, e.g. `_X`, its value is not displayed by the interactive Prolog shell (often called the *top level*)

## Classification of Prolog terms

- The taxonomy of Prolog terms – corresponding built-in predicates (BIPs)

- The five coloured BIPs correspond to the five basic term types.
- Two further type-checking BIPs:
  - `simple(X)`: `X` is not compound, i.e. it is a variable or a constant.
  - `ground(X)`: `X` is a constant or a compound with no (uninstantiated) variables in it.

## Another syntactic “sweetener” – list notation

- A Prolog *list* `[a,b,...]` represents a sequence of terms (cf. linked list)
 

```
| ?- L = [a,b,c], write_canonical(L).
'. '(a, '. '(b, '. '(c, []))'
```

(Since version 7, SWI Prolog uses `'[]'`, instead of `'.' :(((.`)

- The *head* of a list is its first element, e.g. `L`'s head: `a`  
the *tail* is the list of all but the first element, e.g. `L`'s tail: `[b,c]`
- One often needs to split a list to its head and tail: `List = .(Head, Tail).`  
The “square bracketed” counterpart: `List = [Head|Tail]`
- Further sweeteners: `[E1,E2,...,EN|Tail] ≡ [E1|[E2|...,[EN|Tail]...]]`  
`[E1,E2,...,EN] ≡ [E1,E2,...,EN|[]]`

## Open ended and proper lists

- Example:

```
% head0(L): L's first element is 0.
head0(L) :- L = [0|_]. % '_' is a void, don't care variable

% singleton(L): L has a single element.
singleton([_]).

| ?- singleton(L1). => L1 = [_A] % L1 = [_A|[]] is a proper list
| ?- head0(L2). => L2 = [0|_A] % L2 is an open ended list
```

- A Prolog term is called an *open ended* (or *partial*) list iff
  - either it is an unbound variable,
  - or it is a nonempty list structure (i.e. of the form `[_|_]`) and its tail is *open ended*,
 i.e. if sooner or later an unbound variable appears as the tail.
- A list is *closed* or *proper* iff sooner or later an `[]` appears as the tail
- Further examples: `[X,1,Y]` is a proper list, `[X,1|Z]` is open ended.

## Working with lists – some practice

(Each occurrence of a void variable (`_`) denotes a different variable.)

```
| ?- [1,2] = [X|Y]. => X = 1, Y = [2] ?
| ?- [1,2] = [X,Y]. => X = 1, Y = 2 ?
| ?- [1,2,3] = [X|Y]. => X = 1, Y = [2,3] ?
| ?- [1,2,3] = [X,Y]. => no
| ?- [1,2,3,4] = [X,Y|Z]. => X = 1, Y = 2, Z = [3,4] ?
| ?- L = [a,b], L = [_X|_]. => ..., X = b ? % X = 2nd elem
| ?- L = [a,b], L = [_X,_|_]. => no ? % length >= 3, X = 2nd elem
| ?- L = [1|_], L = [_2|_]. => L = [1,2|_A] ? % open ended list
```

## Programming with lists – simple example

- Recall: I/O mode notation for pred. arguments (*only* in comments):
  - `+`: input (bound), `-`: output (unbound var.), `?`: arbitrary.
- Write a predicate that checks if all elements in a list are the same. Let's call such a list *A-boring*, where *A* is the element appearing repeatedly.
 

```
% boring(+L, ?A): List L is A-boring.
```
- Transform the following English statements to Prolog clauses
  - `[]` is *A-boring* for every *A*
  - List *L* is *A-boring*, if
    - *L*'s head equals *A* and
    - *L*'s tail is *A-boring*.
- Remember, you can read `:-` as 'if', `,` as 'and'

## Programming with lists – further examples

- Given a list of numbers, calculate the sum of the list elements.
 

```
% sum(+L, ?Sum): L sums to Sum. (L is a list of numbers.)
```

  - Transform the following English statements to Prolog clauses
    - `[]` sums to 0.
    - A list with head *H* and tail *T* sums to *Sum* if
      - *T* sums to *Sum0* and
      - *Sum* is the value of *Sum0+H*.
    - Remember, you can do arithmetic calculations with 'is'
  - Given two arbitrary lists, check that they are of equal length.
 

```
% same_length(?L1, ?L2): Lists L1 and L2 are of equal length.
```

    - Transform the following English statements to Prolog clauses
      - `[]` has the same length as `[]`
      - *L1* and *L2* are of equal length if
        - the tail of *L1* and the tail of *L2* are of equal length.

## Another recursive data structure – binary tree

- A binary tree data structure can be defined as being
  - either a leaf (`leaf`) which contains an integer (`value`)
  - or a node (`node`) which contains two subtrees (`left`, `right`)
- Defining binary tree structures in C and Prolog:

```
% Declaration of a C structure
enum treetype Leaf, Node;
struct tree {
    enum treetype type;
    union {
        struct { int value;
                } leaf;

        struct { struct tree *left;
                struct tree *right;
                } node;
    } u;
};
```

```
% No need to define types in Prolog
% A type-checking predicate can be
% written, if this check is needed:

% is_tree(T): T is a binary tree
is_tree(leaf(Value)) :-
    integer(Value).
is_tree(node(Left,Right)) :-
    is_tree(Left),
    is_tree(Right).
```

Recall: `integer(Value)` is a BIP which succeeds if and only if `v` is an integer.

## Calculating the sum of numbers in the leaves of a binary tree

- Calculating the sum of the leaves of a binary tree:
  - if the tree is a leaf, return the integer in the leaf
  - if the tree is a node, add the sums of the two subtrees

```
% C function (declarative)
int tree_sum(struct tree *tree) {
    switch(tree->type) {
        case Leaf:
            return tree->u.leaf.value;
        case Node:
            return
                tree_sum(tree->u.node.left) +
                tree_sum(tree->u.node.right);
    }
}
```

```
% Prolog procedure
% tree_sum(+T, ?S):
% The sum of the leaves
% of tree T is S.
tree_sum(leaf(Value), S) :-
    S = Value.
tree_sum(node(Left,Right), S) :-
    tree_sum(Left, S1),
    tree_sum(Right, S2),
    S is S1+S2.
```

## Sum of Binary Trees – a sample run

```
% sicstus
SICStus 4.3.5 (...)
| ?- consult(tree).      % alternatively: compile(tree). or [tree].
% consulting /home/szeredi/examples/tree.pl...
% consulted /home/szeredi/examples/tree.pl in module user, (...)
| ?- tree_sum(node(leaf(5),
                    node(leaf(3), leaf(2))), Sum).

Sum = 10 ? ; no
| ?- tree_sum(leaf(10), 10).
yes
| ?- tree_sum(leaf(10), Sum).
Sum = 10 ? ; no
| ?- tree_sum(Tree, 10).
Tree = leaf(10) ? ;
! Instantiation error in argument 2 of is/2
! goal: 10 is _73+_74
| ?- halt.
```

The cause of the error: the built-in arithmetic is one-way: the goal `10 is S1+S2` causes an error!

## Contents

- 2 Declarative Programming with Prolog
  - Prolog – first steps
  - Prolog execution models
  - The syntax of the (unsweetened) Prolog language
  - Further control constructs
  - Operators and special terms
  - Working with lists
  - Term ordering
  - Higher order predicates
  - All solutions predicates
  - Efficient programming in Prolog
  - Executable specifications
  - Further reading

## Two Prolog execution models

- The **Goal Reduction** model
  - a reformulation of the resolution proof technique
  - good for visualizing the search tree
- The **Procedure Box** model
  - reflects actual implementation better
  - used by the Prolog trace mechanism

## Goal reduction vs. resolution – a propositional example

```

get_fined :-    driving_fast, raining.      (1)
driving_fast :- in_a_hurry.                (2)
...
in_a_hurry.    (3)
raining.       (4)

```

- To show that the goal `get_fined` holds, goal reduction repeatedly *reduces* it to other goals using clauses (1)–(4)
- When an empty goal (`true`) is obtained the goal gets proved.

```

(g1) get_fined           % (g1) is reduced, using (1), to   (g2)
(g2) driving_fast, raining % (g2) is reduced, using (2), to   (g3)
(g3) in_a_hurry,  raining % (g3) is reduced, using (3), to   (g4)
(g4) raining           % (g4) is reduced, using (4), to   (g5)
(g5) ■ (empty goal) ≡ true

```

## Goal reduction vs. resolution (cnt'd)

```

+get_fined      -driving_fast -raining.      (1)
+driving_fast   -in_a_hurry                  (2)
...
+in_a_hurry.    (3)
+raining.       (4)

```

- To show that `get_fined` holds, resolution does an indirect proof
- Assume `get_fined` does not hold, deduce false (contradiction) using clauses (1)–(4)

```

(g1) -get_fined           % (g1) and           (1) implies (g2)
(g2) -driving_fast -raining % (g2) and           (2) implies (g3)
(g3) -in_a_hurry  -raining % (g3) and           (3) implies (g4)
(g4) -raining           % (g4) and           (4) implies (g5)
(g5) □ (empty clause) ≡ false

```

## The Goal Reduction model – the grandparent example

- Goal reduction takes a goal, i.e. a *conjunction* of subgoals  $G$  and using a clause  $C$  reduces it to goal  $G'$ ,

so that  $G' \rightarrow G$   
using (gp1) gives

- E.g. reducing  $G = \text{has\_gp}(b, X)$   
 $G' = \text{has\_p}(b, P1), \text{has\_p}(P1, X)$

```

has_p(b, c).      % (p1)
has_p(b, d).      % (p2)
has_p(d, e).      % (p3)
has_p(d, f).      % (p4)

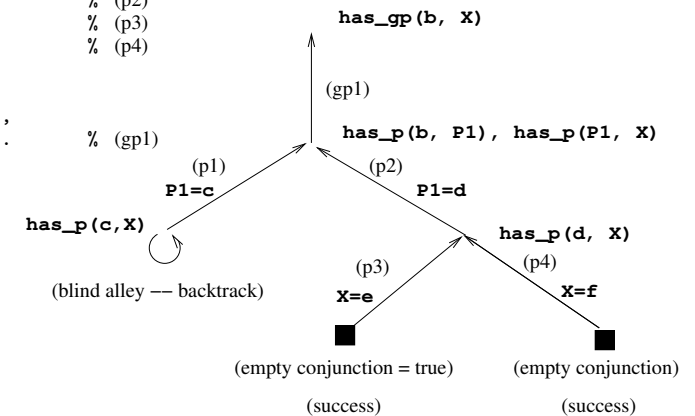

```

```

has_gp(GC, GP) :-
  has_p(GC, P),
  has_p(P, GP).    % (gp1)

```

| ?- has\_gp(b, X).

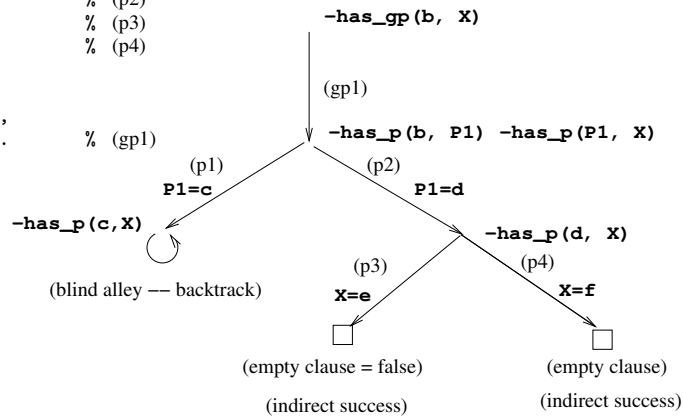

## Resolution – same example

- Resolution takes a negated goal  $NG$  (which is a *disjunction* of neg. literals) and using a clause  $C$  deduces new negated goal  $NG'$ , so that  $NG \rightarrow NG'$
- E.g. resolving  $NG = \text{-has\_gp}(b, X)$  using (gp1) gives  
 $NG' = \text{-has\_p}(b, P1) \text{-has\_p}(P1, X)$

```
+has_p(b, c).      % (p1)
+has_p(b, d).      % (p2)
+has_p(d, e).      % (p3)
+has_p(d, f).      % (p4)
```

```
+has_gp(GC, GP)
  -has_p(GC, P),
  -has_p(P, GP).   % (gp1)
```

```
-has_gp(b, X).
```

## The Goal Reduction model (ADVANCED)

Goal reduction: a goal is viewed as a conjunction of subgoals

- Given a goal  $G = A, B, \dots$  and a clause  $(A :- D, \dots)$   $G' = B, \dots, D, \dots$  is obtained as the new goal

Goal reduction is the same as resolution, but viewed as backwards reasoning

- Resolution:
  - to prove  $A \wedge B \wedge \dots$ , we negate it obtaining  $\neg G_0 = \neg A \neg B \dots$
  - resolution step: clause  $Cl = (+A \neg D \dots)$  resolved with  $\neg G_0$  produces  $\neg G_1 = \neg D \dots \neg B \dots$  (resolution)
  - success of indirect proof: reaching an empty clause  $\square \equiv \text{false}$
- Goal reduction:
  - to prove  $A \wedge B \wedge \dots$ , we start with  $G_0 = A, B, \dots$
  - reduction step: using  $Cl = (A :- D, \dots)$  one can reduce  $G_0$  to  $G_1 = D, \dots, B, \dots$  (reduction)
  - success of the reduction proof: reaching an empty goal  $\blacksquare \equiv \text{true}$
- the (resolution) and (reduction) reasoning rules are equivalent!

## The definition of a goal reduction step

Reduce a goal  $G$  to a new goal  $G'$  using a program clause  $Cl_i$ :

- Split goal  $G$  into the first subgoal  $G_F$  and the residual goal  $G_R$
- Copy** clause  $Cl_i$ , i.e. rename all variables to new ones, and split the copy to a head  $H$  and body  $B$
- Unify** the goal  $G_F$  and the head  $H$ 
  - If the unification fails, exit the reduction step with failure
  - If the unification succeeds with a substitution  $\sigma$ , return the new goal  $G' = (B, G_R)\sigma$  (i.e. apply  $\sigma$  to both the body and the residual goal)

E.g., slide 105:  $G = \text{has\_gp}(b, X)$  using (gp1)  $\Rightarrow G' = \text{has\_p}(b, P1), \text{has\_p}(P1, X)$

Reduce a goal  $G$  to a new goal  $G'$  by executing a built-in predicate (BIP)

- Split goal  $G$  into the first, BIP subgoal  $G_F$  and the residual goal  $G_R$
- Execute** the BIP  $G_F$ 
  - If the BIP fails then exit the reduction step with failure
  - If the BIP succeeds with a substitution  $\sigma$  then return the new goal  $G' = G_R\sigma$

## The goal reduction model of Prolog execution – outline

- This model describes how Prolog builds and traverses a search tree
- A web app for practicing the model: <https://ait.plwin.dev/P1-1>
- The inputs:
  - a Prolog program (a sequence of clauses), e.g. the `has_gp` program
  - a goal, e.g. `:- has_gp(b, GP).` extended with a special goal, carrying the solution: `answer(Sol):`

```
:- has_gp(b, GP), answer(GP).      % Who are the grandparents of a?
:- has_gp(Ch, GP), answer(Ch-GP). % Which are the child-parent pairs?
```
- When only an `answer` goal remains, a solution is obtained
- Possible outcomes of executing a Prolog goal:
  - Exception (error), e.g. `:- Y = apple, X is Y+1.` (This is not discussed further here)
  - Failure (no solutions), e.g. `:- has_p(c, P), answer(P).`
  - Success (1 or more solutions), e.g. `:- has_p(d, P), answer(P).`

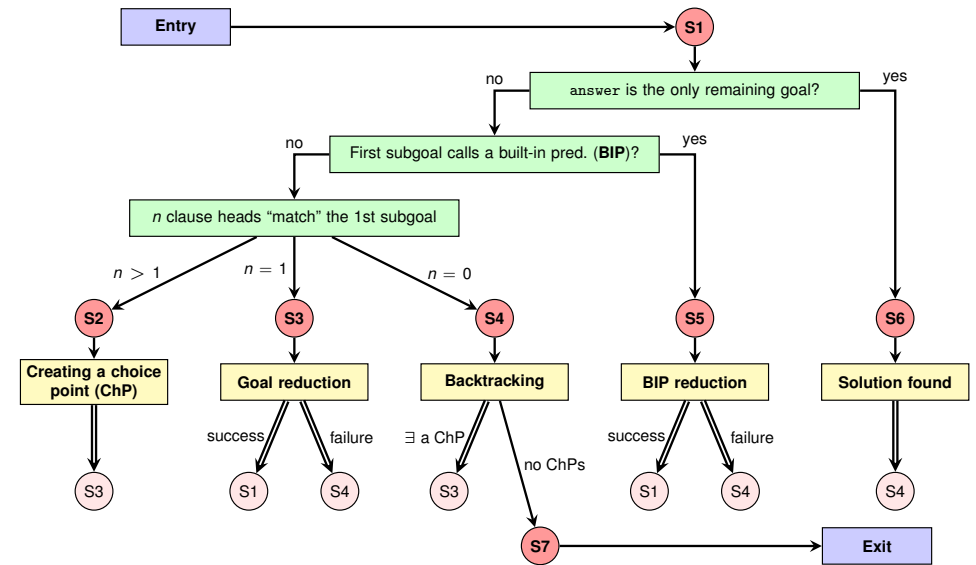

## The main data structures used in the model

- There are only two (imperative, mutable) variables in this model:
  - Goal**: the current goal sequence, **ChPSt** the stack of choice points (ChPs)
- If, in a reduction step, two or more clause heads unify (match) the first subgoal, a new **ChPSt** entry is made, storing:
  - the list of clauses with possibly matching heads
  - the current goal sequence (i.e. **Goal**)

| ChPoint name | Clause list | Goal                                     |
|--------------|-------------|--|
| CHP2         | [p3,p4]     | (4) hasP(d, Y), answer(b-Y).             |
| CHP1         | [p2,p3,p4]  | (2) hasP(X, P), hasP(P, Y), answer(X-Y). |

- At a failure, the top entry of the **ChPSt** is examined:
  - the goal stored there becomes the current **Goal**,
  - the first element of the list of clauses is removed, the second is remembered the as the “**current clause**”,
  - if the list of clauses is now a singleton, the top entry is removed,
  - finally the **Goal** is reduced, using the **current clause**.
- If, at a failure, **ChPSt** is empty, execution ends.

## The flowchart of the Prolog goal reduction model

(Double arrows indicate a jump to the step in the pink circle, i.e. execution continues at the given red circle.)

## Remarks on the flowchart

- There are seven different execution steps: **S1–S7**, where **S1** is the initial (but also an intermediate) step, and **S7** represents the final state.
- The main task of **S1** is to branch to one of **S2–S6**:
  - when **Goal** contains an **answer** goal only ⇒ **S6**;
  - when the first subgoal of **Goal** calls a BIP ⇒ **S5**;
  - otherwise the first subgoal calls a user predicate. Here a set of clauses is selected which *contains* all clauses whose heads match the first subgoal (this may be a *superset* of the matching ones). Based on the number of clauses ⇒ **S2**, **S3** or **S4**.
- S2** creates a new **ChPSt** entry, and ⇒ **S3** (to reduce with the first clause).
- S3** performs the reduction. If that fails ⇒ **S4**, otherwise ⇒ **S1**.
- S4** retrieves the next clause from the top **ChPSt** entry, if any (⇒ **S3**), otherwise execution ends (⇒ **S7**).
- In **S5**, similarly to **S3**, if the BIP succeeds ⇒ **S1**, otherwise ⇒ **S4**.
- In **S6**, the solution is displayed and further solutions are sought (⇒ **S4**).

## The Procedure Box execution model – example

- The **procedure box** execution model of **has\_gp**

```
has_gp(GC, GP) :- has_p(GC, P), has_p(P, GP).
```

```
has_p(b, c).
has_p(b, d).
has_p(d, e).
has_p(d, f).
```

## Prolog tracing, based on the four port box model

```
| ?- consult(gp3).
% consulting gp3.pl...
% consulted gp3.pl ...
yes
| ?- listing.
has_gp(Ch, G) :-
    has_p(Ch, P),
    has_p(P, G).

has_p(b, c).
has_p(b, d).
has_p(d, e).
has_p(d, f).

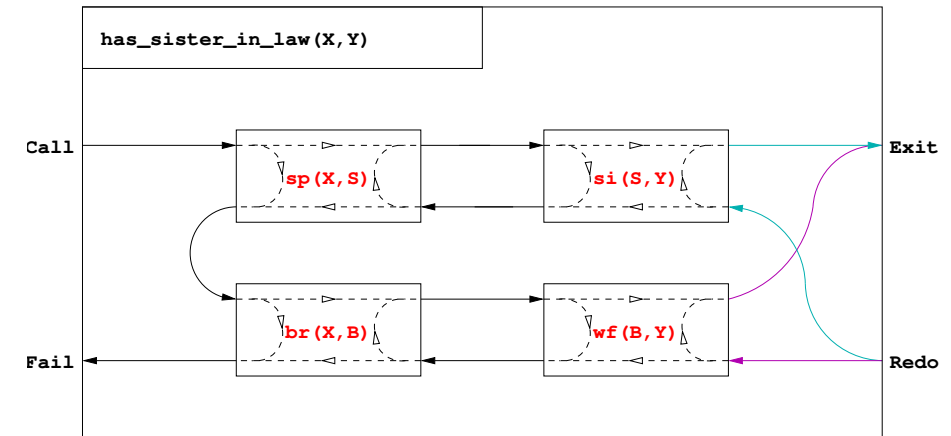

yes
| ?- trace.
% The debugger will ...
yes
```

```
| ?- has_gp(Ch, f).
Det? BoxId Depth Port Goal
1 1 1 Call: has_gp(Ch,f) ?
2 2 2 Call: has_p(Ch,P) ?
? 2 2 Exit: has_p(b,c) ?
3 3 2 Call: has_p(c,f) ?
3 2 Fail: has_p(c,f) ?
? 2 2 Redo: has_p(b,c) ?
? 2 2 Exit: has_p(b,d) ?
4 4 2 Call: has_p(d,f) ?
4 2 Exit: has_p(d,f) ?
No choice left in box 4, box removed (no ?)
? 1 1 Exit: has_gp(b,f) ?
Ch = b ? ;
1 1 Redo: has_gp(b,f) ?
2 2 Redo: has_p(b,d) ?
? 2 2 Exit: has_p(d,e) ?
5 2 Call: has_p(e,f) ?
5 2 Fail: has_p(e,f) ?
2 2 Redo: has_p(d,e) ?
2 2 Exit: has_p(d,f) ?
No choice left in box 2, box removed (no ?)
6 2 Call: has_p(f,f) ?
6 2 Fail: has_p(f,f) ?
1 1 Fail: has_gp(Ch,f) ?
no
| ?-
```

## The procedure-box of multi-clause predicates

'Sister in law' can be one's spouse's sister; or one's brother's wife:

```
has_sister_in_law(X, Y) :-
    has_spouse(X, S), has_sister(S, Y).
has_sister_in_law(X, Y) :-
    has_brother(X, B), has_wife(B, Y).
```

## The procedure-box of a "database" predicate of facts

- In general in a multi-clause predicate the clauses have different heads
- A database of facts is a typical example:

```
has_p(b, c).
has_p(b, d).
```

- These clauses can be massaged to have the same head:

```
has_p(Ch, P) :- Ch = b, P = c.
has_p(Ch, P) :- Ch = b, P = d.
```

- Consequently, the procedure-box of this predicate is this:

## Summary – syntax of Prolog predicates, clauses

### Example

```
% A predicate with two clauses, the functor is: tree_sum/2
tree_sum(leaf(Val), Val).           % clause 1, fact
tree_sum(node(Left,Right), S) :- % head \
    tree_sum(Left, S1),           % goal \ |
    tree_sum(Right, S2),         % goal | body | clause 2, rule
    S is S1+S2.                 % goal / |
```

### Syntax

```
<program> ::= <predicate> ... {i.e. a sequence of predicates}
<predicate> ::= <clause> ... {with the same functor}
<clause> ::= <fact> .␣ |
            <rule> .␣
<fact> ::= <head>
<rule> ::= <head> :- <body> {clause functor = head functor}
<body> ::= <goal>, ... {i.e. a seq. of goals sep. by commas}
<head> ::= <callable term> {atom or compound}
<goal> ::= <callable term> {or a variable, if instantiated to a callable}
```

## Prolog terms (canonical form)

### Example – a clause head as a term

```
% tree_sum(node(Left,Right), S) % compound term, has the
% ----- - % functor tree_sum/2
% | | |
% compound name \ argument, variable
% \ - argument, compound term
```

### Syntax

```
<term> ::= <variable> | {has no functor}
         <constant> | {{constant}/0}
         <compound term> | {{comp. name}/<# of args>}
         ... extensions ... {lists, operators}
<constant> ::= <atom> | {symbolic constant}
              <number>
<number> ::= <integer> | <float>
<compound term> ::= <comp. name> (<argument>, ...)
<comp. name> ::= <atom>
<argument> ::= <term>
<callable term> ::= <atom> | <compound term>
```

## Lexical elements

### Examples

```
% variable: Fact FACT _fact X2 _2 _
% atom: fact ≡ 'fact' 'István' [] ; ', ' += ** \= ≡ '\\='
% number: 0 -123 10.0 -12.1e8
% not an atom: !=, István
% not a number: 1e8 1.e2
```

### Syntax

```
<variable> ::= <capital letter><alphanum>... |
             _ <alphanum>...
<atom> ::= ' <quoted char>... ' |
           <lower case letter><alphanum>... |
           <sticky char>... | ! | ; | [] | {}
<integer> ::= {signed or unsigned sequence of digits}
<float> ::= {a sequence of digits with a compulsory decimal point
            in between, with an optional exponent}
<quoted char> ::= {any non ' and non \ character} | \ <escaped char>
<alphanum> ::= <lower case letter> | <upper case letter> | <digit> | _
<sticky char> ::= + | - | * | / | \ | $ | ^ | < | > | = | ' | ~ | : | . | ? | @ | # | &
```

## Comments and layout in Prolog

- Comments
  - From a % character till the end of line
  - From /\* till the next \*/
- Layout (spaces, newlines, tabs, comments) can be used freely, except:
  - No layout allowed between the name of a compound and the “(”
  - If a prefix operator (see later) is followed by “(”, these have to be separated by layout
  - Clause terminator (.␣): a stand-alone full stop (i.e., one not preceded by a sticky char), followed by layout
- The recommended formatting of Prolog programs:
  - Write clauses of a predicate continuously, no empty lines between
  - Precede each pred. by an empty line and a spec (head comment)
 

```
% predicate_name(A1, ..., An): A declarative sentence (statement)
% describing the relationship between terms A1, ..., An
```
  - Write the head of the clause at the beginning of a line, and prefix each goal in the body with an indentation of a few (8 recommended) spaces.

## Disjunctions

- Disjunctions (i.e. subgoals separated by “or”) can appear as goals
- A disjunction is denoted by semicolon (“;”)
- Enclose the **whole** disjunction in parentheses, align chars (, ; and )

```
has_sister_in_law(X, Y) :-
    (   has_spouse(X, S), has_sister(S, Y)
      ; has_brother(X, B), has_wife(B, Y)
    ).
```

- The above predicate is equivalent to:

```
has_sister_in_law(X, Y) :- has_spouse(X, S), has_sister(S, Y).
has_sister_in_law(X, Y) :- has_brother(X, B), has_wife(B, Y).
```

- A disjunction is itself a valid goal, it can appear in a conjunction:

```
has_ancestor(X, A) :-
    has_parent(X, P), (   A = P
                       ; has_ancestor(P, A)
                       ).
```

Can you make an equivalent variant which does not use “;”?

## Disjunctions, continued

- An example with multiple disjunctions:

```
% first_1(L): the first nonzero element of L is 1.
first_1([A,B,C]) :-
    (   A = 1
      ; A = 0,
        (   B = 1
          ; B = 0, C = 1
        )
    ).
```

- Note: the  $v=Term$  goals can no longer be got rid of in disjunctions
- Comma binds more tightly than semicolon, e.g.
 

```
p :- ( q, r ; s ) ≡ p :- ((q, r) ; s).
```

 Please, never enclose disjuncts (goals on the sides of ;) in parentheses!
- You can have more than two-way “or”s:
 

```
p :- ( a ; b ; c ; ... )
```

 which is the same as
 

```
p :- ( a ; (b ; (c ; ...)) )
```
- Please, do not use the unnecessary parentheses (colored red)!

## Expanding disjunctions to helper predicates

- Example:  $p :- q, (r ; s).$

Distributive expansion inefficient, as it calls  $q$  twice:
 

```
p :- q, r.
p :- q, s.
```

- For an efficient solution introduce a helper predicate. Example:

```
t(X, Z) :-
    p(X, Y),
    (   q(Y, U), r(U, Z)
      ; s(Y, Z)
      ; t(Y), w(Z)
    ),
    v(X, Z).
```

- Collect variables that occur both inside and outside the disj. –  $Y, Z.$
- Define a helper predicate –  $aux(Y, Z)$  – with these vars as args, transform each disjunct to a separate clause of the helper predicate:
 

```
aux(Y, Z) :- q(Y, U), r(U, Z).
aux(Y, Z) :- s(Y, Z).
aux(Y, Z) :- t(Y), w(Z).
```
- Replace the disjunction with a call of the helper predicate:
 

```
t(X, Z) :- p(X, Y), aux(Y, Z), v(X, Z).
```

## The if-then-else construct

- When the two branches of a disjunction exclude each other, use the if-then-else construct ( `condition -> then ; else` ). Example:

```
% pow(A, E, P): P is A to the power E.
pow(A, E, P) :-
  ( E > 0, E1 is E-1, =>
    pow(A, E1, P1),
    P is A*P1
  ; E = 0, P = 1
  ).

pow1(A, E, P) :-
  ( E > 0 -> E1 is E-1,
    pow(A, E1, P1),
    P is A*P1
  ; E = 0, P = 1
  ).
```

- `pow1` is about 25% faster than `pow` and requires much less memory
- The atom `->` is a standard operator
- The construct ( `Cond -> Then ; Else` ) is executed by first executing `Cond`. If this succeeds, `Then` is executed, otherwise `Else` is executed.
- Important:** Only the **first** solution of `Cond` is used for executing `Then`. The remaining solutions are **discarded!**
- Note that ( `Cond -> Then ; Else` ) looks like a disjunction, but it is not
- The else-branch can be omitted, it defaults to `false`.

## Defining “childless” using if-then-else

- Given the `has_parent/2` predicate, define the notion of a `childless` person
- If we can find a child of a GIVEN person, then `childless` should fail, otherwise it should succeed.

```
% childless(+Person): A given Person has no children
childless(Person) :-
  ( has_parent(_, Person) -> fail
  ; true
  ).
```

- What happens if you call `childless(P)`, where `P` is an unbound var? Will it enumerate `childless` people in `P`? No, it will simply fail.
- The above if-then-else can be simplified to:
 

```
childless(Person) :- \+ has_parent(_, Person).
```
- “\+” is called Negation by Failure, “\+ `G`” runs by executing `G`:
  - if `G` fails “\+ `G`” succeeds.
  - if `G` succeeds “\+ `G`” fails (ignoring further solutions of `G`, if any)
- Since a failed goal produces no bindings, “\+ `G`” will never bind a variable.
- Read “\+” as “not provable”, cf.  $\not\vdash$  tilted slightly to the left.

## Open and closed world assumption

```
has_parent(a, b). has_parent(a, c). has_parent(c, d).      (1)-(3)
```

- Does (1)-(3) imply that `a` is `childless`:  $\varphi = \forall X. \neg \text{has\_parent}(X, a)$ ?
- No. Although `has_parent(Ch, a)` cannot be proven,  $\varphi$  does not hold!
- But in the world of databases we do conclude that `a` is `childless`...
- Databases use the Closed World Assumption (CWA): anything that cannot be proven is considered false.
- Mathematical logic uses the Open World Assumption (OWA)
  - A statement `S` follows from a set of statements `P` (premises), if `S` holds in any world (interpretation) that satisfies `P`.
  - thus  $\varphi$  is not a logical consequence of (1)-(3)
- Classical logic (OWA) is monotonic: the more you know, the more you can deduce
- Negation by failure (CWA) is non-monotonic: add the fact “`has_parent(e, a).`” to (1)-(3) and `\+ has_parent(_, a)` will fail.

## Checking inequality – siblings and cousins

```
has_p('Charles', 'Elizabeth'). has_p('Andrew', 'Elizabeth').
has_p('William', 'Charles'). has_p('Beatrice', 'Andrew').
has_p('Harry', 'Charles'). has_p('Eugenie', 'Andrew').
```

- Recall homework L4, define predicate `has_sibling/2`, first attempt:
 

```
has_sibling0(A, B) :- \+ A = B, has_p(A, P), has_p(B, P).
```
- `has_sibling0` does **not** work properly, e.g. this goal fails:
 

```
| ?- has_sibling0('Charles', X).
```

 because `\+ 'Charles' = X` fails (as `'Charles' = X` succeeds)
- Negated goals should be instantiated as much as possible, therefore always place them at the end of the body:
 

```
has_sibling(A, B) :- has_p(A, P), has_p(B, P), \+ A = B.
```
- Define `has_cousin/2` (using `has_gp/2`, the “has grandparent” predicate)
 

```
has_cousin(A, B) :-
  has_gp(A, GP), has_gp(B, GP), \+ has_sibling(A, B), A \= B.
```
- Note that the BIP `A \= B` is equivalent to `\+ A = B`

## The relationship of if-then-else and negation

- Negation can be **fully** defined using if-then-else

```

\+ p           ≡      ( p -> false
                    ; true
                    )
  
```

- If-then-else can be transformed to a disjunction with a negation:

```

( cond -> then
; else
)           ⇒      ( cond, then
                    ; \+ cond, else
                    )
  
```

These are equivalent only if `cond` succeeds at most once.

The if-then-else is more efficient (no choice point left).

- As semicolon is associative, there is no need to use nested parentheses (...) if multiple if-then-else branches are present (and please don't):

```

( cond1 -> then1
; ( cond2 -> then2
; ( ... )
)
; else
)           ⇒      ( cond1 -> then1
                    ; cond2 -> then2
                    ; (...)
                    ; else
                    )
  
```

## The procedure-box of disjunctions

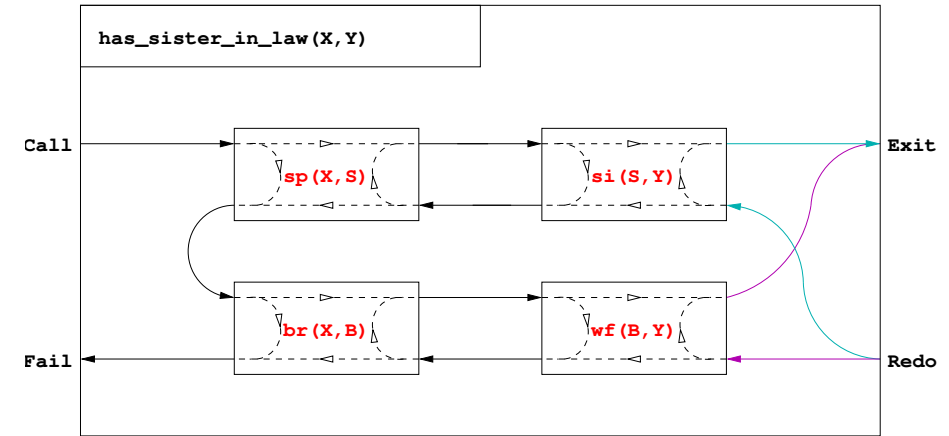

A disjunction can be transformed into a multi-clause predicate

```

has_sister_in_law(X, Y) :-
( has_spouse(X, S), has_sister(S, Y)
; has_brother(X, B), has_wife(B, Y)
).
  
```

```

has_sister_in_law(X, Y) :-
has_spouse(X, S), has_sister(S, Y).
has_sister_in_law(X, Y) :-
has_brother(X, B), has_wife(B, Y).
  
```

## The procedure box for if-then-else

```

% ha(+N, ?D, ?A): D has A as their Nth generation ancestor (N>0 int)
% The 1st, 2nd, 3rd generation ancestors are
% parents, grandparents, great-grandparents etc.
ha(N, D, A) :-
( N = 1 -> hp(D, A) % hp(D, A): D has a parent A
; N > 1, M is N-1, hp(D, P), ha(M, P, A)
).
  
```

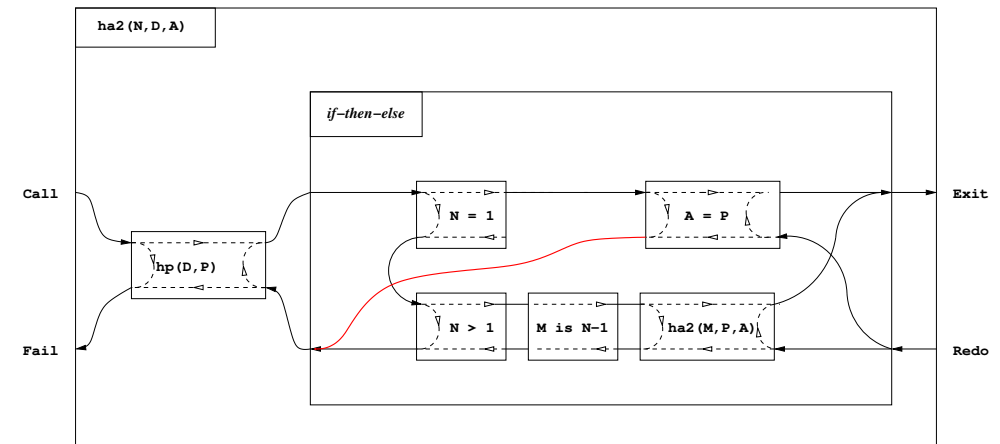

- Failure of the **"then"** part leads to failure of the **whole** if-then-else construct

## The if-then-else box, continued

- When an if-then-else occurs in a conjunction, or there are multiple clauses, then it requires a separate box

```

ha2(N, D, A) :- hp(D, P), ( N = 1 -> A = P
                           ; N > 1, M is N-1, ha2(M, P, A)
                           ).
  
```

### 2 Declarative Programming with Prolog

- Prolog – first steps
- Prolog execution models
- The syntax of the (unsweetened) Prolog language
- Further control constructs
- Operators and special terms
- Working with lists
- Term ordering
- Higher order predicates
- All solutions predicates
- Efficient programming in Prolog
- Executable specifications
- Further reading

## Introducing operators

- Example:  $s$  is  $-s_1+s_2$  is equivalent to:  $is(s, +(-s_1),s_2)$
- Syntax of terms using operators
  - $\langle \text{comp. term} \rangle ::=$ 
    - $\langle \text{comp. name} \rangle ( \langle \text{argument} \rangle, \dots )$  {so far we had this}
    - $\langle \text{argument} \rangle \langle \text{operator name} \rangle \langle \text{argument} \rangle$  {infix term}
    - $\langle \text{operator name} \rangle \langle \text{argument} \rangle$  {prefix term}
    - $\langle \text{argument} \rangle \langle \text{operator name} \rangle$  {postfix term}
    - $( \langle \text{term} \rangle )$  {parenthesized term}
  - $\langle \text{operator name} \rangle ::= \langle \text{comp. name} \rangle$  {if declared as an operator}
- The built-in predicate for defining operators:
  - $op(\text{Priority}, \text{Type}, \text{Op})$  Or  $op(\text{Priority}, \text{Type}, [\text{Op}_1, \text{Op}_2, \dots])$ :
    - Priority: an int. between 1 and 1200 – smaller priorities bind tighter
    - Type determines the placement of the operator and the associativity:
      - infix:  $yfx, xfy, xfx$ ; prefix:  $fy, fx$ ; postfix:  $yf, xf$  ( $f$  – op,  $x, y$  – args)
      - $\text{Op}$  or  $\text{Op}_i$ : an arbitrary atom
  - The call of the BIP  $op/3$  is normally placed in a **directive**, executed immediately when the program file is loaded, e.g.:
 

```
:- op(800, xfx, [has_tree_sum]).      leaf(V) has_tree_sum V.
```

## Characteristics of operators

### Operator properties implied by the operator type

| Type        |              |            | Class   | Interpretation         |
|-------------|--------------|------------|---------|------------------------|
| left-assoc. | right-assoc. | non-assoc. |         |                        |
| $yfx$       | $xfy$        | $xfx$      | infix   | $X f Y \equiv f(X, Y)$ |
|             | $fy$         | $fx$       | prefix  | $f X \equiv f(X)$      |
| $yf$        |              | $xf$       | postfix | $X f \equiv f(X)$      |

### Parentheses implied by operator priorities and associativities

- $a/b+c*d \equiv (a/b)+(c*d)$  as the priority of  $/$  and  $*$  (400) is less than the priority of  $+$  (500) **smaller priority = stronger binding**
- $a-b-c \equiv (a-b)-c$  as operator  $-$  has type  $yfx$ , thus it is left-associative, i.e. it binds to the left, the leftmost operator is parenthesized first **(the position of  $y$  wrt.  $f$  shows the direction of associativity)**
- $a^b^c \equiv a^(b^c)$  as  $^$  has type  $xfy$ , therefore it is right-associative
- $a=b=c \implies$  syntax error, as  $=$  has type  $xfx$ , it is non-associative
- the above also applies to different operators of same type and priority:  
 $a+b-c+d \equiv ((a+b)-c)+d$

## Standard built-in operators

### Standard operators

```

1200  xfx  :- -->
1200  fx   :- ?-
1100  xfy  ;
1050  xfy  ->
1000  xfy  ', '
900   fy   \+
700   xfx  = \= =..
      < < =: = =\=
      > >= is
      == \==
      @< @=< @> @>=
500   yfx  + - /\ \\/
400   yfx  * / // rem
      mod << >>
200   xfx  **
200   xfy  ^
200   fy   - \

```

### Further built-in operators of SICStus Prolog

```

1150  fx   mode public dynamic
      volatile discontinuous
      initialization multifile
      meta_predicate block
1100  xfy  do
900   fy   spy nospy
550   xfy  :
500   yfx  \
200   fy   +

```

## Operators – additional comments

- The “comma” is heavily overloaded:
  - it separates the arguments of a compound term
  - it separates list elements
  - it is an xfy op. of priority 1000, e.g.:  
 $(p:-a,b,c) \equiv -(p, ', '(a, ', '(b,c)))$
- Ambiguities arise, e.g. is  $p(a,b,c) \stackrel{?}{\equiv} p((a,b,c))$ ?
- Disambiguation: if the outermost operator of a compound argument has priority  $\geq 1000$ , then it should be enclosed in parentheses

```
| ?- write_canonical((a,b,c)). => ', '(a, ', '(b,c))
```

```
| ?- write_canonical(a,b,c). => Error: ! write_canonical/3 does not exist
```

```
| ?- write_canonical((hgp(A,B):-hp(A,C),hp(C,B))).
```

```
=> :-(hgp(A,B), ', '(hp(A,C),hp(C,B)))
```

- Note: an unquoted comma (,) is an operator, but **not** a valid atom

## Functions and operators allowed in arithmetic expressions

- The Prolog standard prescribes that the following functions can be used in arithmetic expressions:

*plain arithmetic:*

+X, -X, X+Y, X-Y, X\*Y, X/Y,  
 X//Y (int. division, truncates towards 0),  
 X div Y (int. division, truncates towards  $-\infty$ ),  
 X rem Y (remainder wrt. //),  
 X mod Y (remainder wrt. div),  
 X\*\*Y, X^Y (both denote exponentiation)

*conversions:*

float\_integer\_part(X), float\_fractional\_part(X), float(X),  
 round(X), truncate(X), floor(X), ceiling(X)

*bit-wise ops:*

X\Y, X\Y, xor(X,Y), \ X (negation), X<<Y, X>>Y (shifts)

*other:*

abs(X), sign(X), min(X,Y), max(X,Y),  
 sin(X), cos(X), tan(X), asin(X), acos(X), atan(X),  
 atan2(X,Y), sqrt(X), log(X), exp(X), pi

## Uses of operators

- What are operators good for?
  - to allow usual arithmetic expressions, such as in  $X$  is  $(Y+3) \bmod 4$
  - processing of symbolic expressions (such as symbolic derivation)
  - for writing the clauses themselves  
 $(:-, ', ', ; \dots)$  are all standard operators
    - clauses can be passed as arguments to meta-predicates:  
`asserta( (p(X):-q(X),r(X)) )`
  - to make Prolog data structures look like natural language sentences (controlled English), e.g. Smullyan's island of knights and knaves (knights always tell the truth, knaves always lie):  
 We meet natives A and B, A says: one of us is a knave.  
`| ?- solve_puzzle(A says A is a knave or B is a knave).`
  - to make data structures more readable:  
`acid(sulphur, h*2-s-o*4).`

## Classical symbolic computation: symbolic derivation

- Write a Prolog predicate which calculates the derivative of a formula built from numbers and the atom  $x$  using some arithmetic operators.

*% deriv(Formula, D): D is the derivative of Formula with respect to x.*

```
deriv(x, 1).
```

```
deriv(C, 0) :- number(C).
```

```
deriv(U+V, DU+DV) :- deriv(U, DU), deriv(V, DV).
```

```
deriv(U-V, DU-DV) :- deriv(U, DU), deriv(V, DV).
```

```
deriv(U*V, DU*V + U*DV) :- deriv(U, DU), deriv(V, DV).
```

```
| ?- deriv(x*x+x, D). => D = 1*x+x*1+1 ? ; no
```

```
| ?- deriv((x+1)*(x+1), D). => D = (1+0)*(x+1)+(x+1)*(1+0) ? ; no
```

```
| ?- deriv(I, 1*x+x*1+1). => I = x*x+x ? ; no
```

```
| ?- deriv(I, 2*x+1). => no
```

```
| ?- deriv(I, 0). => no
```

- Prolog – first steps
- Prolog execution models
- The syntax of the (unsweetened) Prolog language
- Further control constructs
- Operators and special terms
- Working with lists
- Term ordering
- Higher order predicates
- All solutions predicates
- Efficient programming in Prolog
- Executable specifications
- Further reading

## Concatenating lists

- Let  $L1 \oplus L2$  denote the concatenation of  $L1$  and  $L2$ , i.e. a list consisting of the elements of  $L1$  followed by those of  $L2$ .
- Building  $L1 \oplus L2$  in an imperative language (A list is either a `NULL` pointer or a pointer to a head-tail structure):
  - Scan  $L1$  until you reach a tail which is `NULL`
  - Overwrite the `NULL` pointer with  $L2$
- If you still need the original  $L1$ , you have to copy it, replacing its final `NULL` with  $L2$ . A recursive definition of the  $\oplus$  (concatenation) function:

```
L1  $\oplus$  L2 = if L1 == NULL return L2
           else L3 = tail(L1)  $\oplus$  L2
           return a new list structure whose head is head(L1)
                and whose tail is L3
```

- Transform the above recursive definition to Prolog:

```
% app0(A, B, C): the conc(atenation) of A and B is C
app0([], L2, L2).           % The conc. of [] and L2 is L2.
app0([X|L1], L2, L) :- % The conc. of [X|L1] and L2 is L if
    app0(L1, L2, L3), % the conc. of L1 and L2 is L3 and
    L = [X|L3].        % L's head is X and L's tail is L3.
```

## Efficient and multi-purpose concatenation

- Drawbacks of the `app0/3` predicate:
  - Uses “real” recursion (needs stack space proportional to length of  $L1$ )
  - Cannot split lists, e.g. `app0(L1, [3], [1,3])`  $\rightsquigarrow$  infinite loop
- Apply a generic optimization: eliminate variable assignments
  - Remove goal `var = T`, and replace occurrences of variable `var` by `T`

**Not applicable in the presence of disjunctions or if-then-else**

- Apply this optimization to the second clause of `app0/3`:

```
app0([X|L1], L2, L) :- app0(L1, L2, L3), L = [X|L3].
```

- The resulting code (renamed to `app`, also available as the BIP `append/3`)

```
% app(A, B, C): The conc. of A and B is C, i.e. C = A $\oplus$ B
app([], L2, L2).           % The conc. of [] and L2 is L2.
app([X|L1], L2, [X|L3]) :- % The conc. of [X|L1] and L2 is [X|L3] if
    app(L1, L2, L3).        % the conc. of L1 and L2 is L3.
```

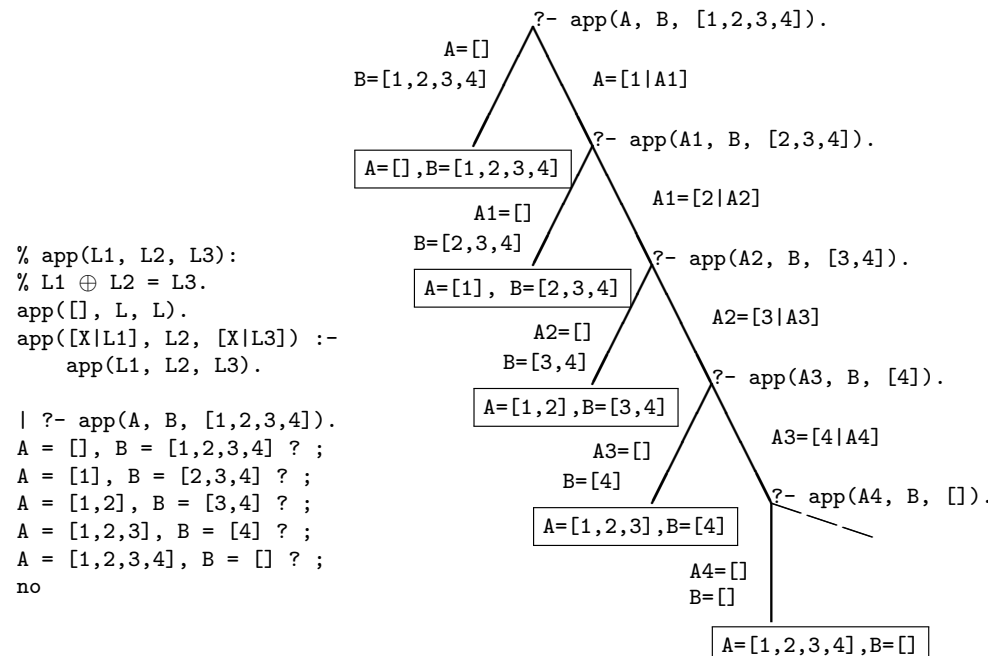

- This uses constant stack space and can be used for multiple purposes, thanks to Prolog allowing **open ended** lists

## Tail recursion optimization

- Tail recursion optimization (TRO), or more generally last call optimization (LCO) is applicable if
  - the goal in question is the last to be executed in a clause body, and
  - no choice points exist in the given predicate.
- LCO is applicable to the recursive call of `app/3`:
 

```
app([], L, L).
app([X|L1], L2, [X|L3]) :- app(L1, L2, L3).
```
- This feature relies on open ended lists:
  - It is possible to build a list node *before* building its tail
  - This corresponds to passing to `append` a pointer to the location where the resulting list should be stored.
- Open ended lists are possible because unbound variables are *first class* objects, i.e. unbound variables are allowed inside data structures. (This type of variable is often called the logic variable).

## Splitting lists using append

How does the “openness” of arguments affect `append(L1,L2,L3)`?

- L2 is never decomposed (“looked inside”) by `append`, whether it is open ended, does not affect execution
- If L1 is closed, `append` produces at most one answer
  - | `?- append([a,b], Tail, L).`  $\implies L = [a,b|Tail] ? ; no$
  - | `?- append([a,b], [c|T], L).`  $\implies L = [a,b,c|T] ? ; no$
  - | `?- append([a,b], [c|T], [_,_d,_]).`  $\implies no$
- If L3 is closed (of length  $n$ ), `append` produces at most  $n + 1$  solutions, where L1 and L2 are closed lists (also see previous slide):
  - | `?- append(L1,L2,[1,2]).`  $\implies L1=[], L2=[1,2] ? ; L1=[1], L2=[2] ? ; L1=[1,2], L2=[] ? ; no$
  - | `?- append([1,2], L, [1,2,3,4,5]).`  $\implies L = [3,4,5] ? ; no$
  - | `?- append(L1, [4|L2], [1,2,3,4,5]).`  $\implies L1 = [1,2,3], L2 = [5] ? ; no$
  - | `?- append(L1, [4,2], [1,2,3,4,5]).`  $\implies no$
- The search may be **infinite**: if **both** the 1st **and** the 3rd arg. is open ended
  - | `?- append([1|L1], [a,b], L3).`  $\implies$
  - $L1 = [], L3 = [1,a,b] ? ;$
  - $L1 = [_A], L3 = [1,_A,a,b] ? ;$
  - $L1 = [_A,_B], L3 = [1,_A,_B,a,b] ? ;$  **ad infinitum** :-((((
  - | `?- append([1|L1], L2, [2|L3]).`  $\implies no$

Eight ways of using `append(L1,L2,L3)` (safe or unsafe)

```

:- mode append(+, +, +). % checking if L1 ⊕ L2 = L3 holds
| ?- append([1,2], [3,4], [1,2,3,4]).  $\implies yes$ 

:- mode append(+, +, -). % appending L1 and L2 to obtain L3
| ?- append([1,2], [3,4], L3).  $\implies L3 = [1,2,3,4] ? ; no$ 

:- mode append(+, -, +). % checking if L1 is a prefix of L3, obtaining L2
| ?- append([1,2], L2, [1,2,3,4]).  $\implies L2 = [3,4] ? ; no$ 

:- mode append(+, -, -). % prepending L1 to an open ended L2 to obtain L3
| ?- append([1,2], [3|L2], L3).  $\implies L3 = [1,2,3|L2] ? ; no$ 

:- mode append(-, +, +). % checking if L2 is a suffix of L3 to obtain L1
| ?- append(L1, [3,4], [1,2,3,4]).  $\implies L1 = [1,2] ? ; no$ 

:- mode append(-, -, +). % splitting L3 to L1 and L2 in all possible ways
| ?- append(L1, L2, [1]).  $\implies L1=[], L2=[1] ? ; L1=[1], L2=[] ? ; no$ 

:- mode append(-, +, -). (see prev. slide) and :- mode append(-, -, -).
| ?- append(L1, L2, L3).  $\implies L1=[], L3=L2 ? ; L1=[A], L3=[A|L2] ? ; L1=[A,B], L3=[A,B|L2] ? \dots$ 

```

Variation on `append` — appending three lists

- Recall: `append/3` has **finite** search space, if its 1<sup>st</sup> or 3<sup>rd</sup> arg. is closed. `append(L,_,_)` completes in  $\leq n + 1$  reduction steps when L has length  $n$
- Let us define `append(L1,L2,L3,L123): L1 ⊕ L2 ⊕ L3 = L123`. First attempt:
 

```

append(L1, L2, L3, L123) :-
  append(L1, L2, L12), append(L12, L3, L123).

```

  - Inefficient: `append([1,...,100],[1,2,3],[1], L)` – 203 and not 103 steps...
  - Not suitable for splitting lists – may create an infinite choice point
- An efficient version, suitable for splitting a given list to three parts:
 

```

% L1 ⊕ L2 ⊕ L3 = L123,
% where either both L1 and L2 are closed, or L123 is closed.
append(L1, L2, L3, L123) :-
  append(L1, L23, L123), append(L2, L3, L23).

```

  - L3 can be open ended or closed, it does not matter
  - Note that in the first `append/3` call either L1 or L123 is closed. If L1 is closed, the first `append/3` produces an open ended list:
 

```

| ?- append([1,2], L23, L123).  $\implies L123 = [1,2|L23]$ 

```

## The BIP `length/2` – length of a list

- `length(?List, ?N)`: list `List` is of length `N`

```
| ?- length([4,3,1], Len).      Len = 3 ? ;
                                no
| ?- length(List, 3).          List = [_A,_B,_C] ? ;
                                no
| ?- length([[4,1,3],[2,8,7]], Len). Len = 2 ? ;
                                no
| ?- length(L, N).             L = [], N = 0 ? ;
                                L = [_A], N = 1 ? ;
                                L = [_A,_B], N = 2 ? ;
                                L = [_A,_B,_C], N = 3 ? ...
```
- `length/2` has an infinite search space if the first argument is an open ended list and the second is a variable.

## Appending a list of lists

- Library `lists` contains a predicate `append/2`  
see e.g. <https://www.swi-prolog.org/search?for=append%2F2>  

```
% append(LL, L): LL is a closed list of lists.
%                L is the concatenation of the elements of LL.
```
- Conditions for safe use (finite search space):
  - Each element of `LL` is a closed list
 

```
| ?- append([[1,2],[3],[4,5]], L). => L = [1,2,3,4,5] ? ; no
```
  - `L` is a closed list
 

```
| ?- append([L1,L2,L3], [1,2]), L1 \= [],
           => L1 = [1], L2 = [], L3 = [2] ? ;
              L1 = [1], L2 = [2], L3 = [] ? ;
              L1 = [1,2], L2 = [], L3 = [] ? ; no
```
- Finding a sublist matching a given pattern:
 

```
| ?- Pattern = [_A,_,_A], append([_Pref,Pattern,_],[1,2,3,2,1,2]),
           length(_Pref, Index).      % obtain the index of the Pattern
Pattern = [2,3,2], Index = 1 ? ;     % Index is zero-based
Pattern = [2,1,2], Index = 3 ? ; no
```

## Finding list elements – BIP `member/2`

- ```
% member(E, L): E is an element of list L
member(Elem, [Elem|_]).      member1(Elem, [Head|Tail]) :-
member(Elem, [_|Tail]) :-    ( Elem = Head
                             ; member1(Elem, Tail)
                             ).
```
- Mode `member(+,+)` – checking membership
 

```
| ?- member(2, [2,1,2]). => yes          BUT
| ?- member(2, [2,1,2]), R=yes. => R = yes ? ; R = yes ? ; no
```
  - Mode `member(-,+)` – enumerating list elements:
 

```
| ?- member(X, [1,2,3]). => X = 1 ? ; X = 2 ? ; X = 3 ? ; no
| ?- member(X, [1,2,1]). => X = 1 ? ; X = 2 ? ; X = 1 ? ; no
```
  - Finding common elements of lists – with both above modes:
 

```
| ?- member(X, [1,2,3]),
           member(X, [5,4,3,2,3]). => X = 2 ? ; X = 3 ? ; X = 3 ? ; no
```
  - Mode `member(+,-)` – making a term an element of a list (infinite choice):
 

```
| ?- member(1, L). => L = [1|_A] ? ; L = [_A,1|_B] ? ;
                       L = [_A,_B,1|_C] ? ; ...
```
  - The search space of `member/2` is **finite**, if the 2<sup>nd</sup> argument is closed.

## Reversing lists

- Naive solution (quadratic in the length of the list)
 

```
% nrev(L, R): List R is the reverse of list L.
nrev([], []).
nrev([X|L], R) :-
  nrev(L, RL),
  append(RL, [X], R).
```
- A solution which is linear in the length of the list
 

```
% reverse(L, R): List R is the reverse of list L.
reverse(L, R) :- revapp(L, [], R).

% revapp(L1, L2, R): The reverse of L1 prepended to L2 gives R.
revapp([], R, R).
revapp([X|L1], L2, R) :-
  revapp(L1, [X|L2], R).
```
- In SICStus 4 `append/3` is a BIP, `reverse/2` is in library `lists`
- To load the library place this directive in your program file:
 

```
:- use_module(library(lists)).
```

## append and revapp — building lists forth and back (ADVANCED)

## ● Prolog

```
app([], L, L).
app([X|L1], L2, [X|L3]) :-
    app(L1, L2, L3).

revapp([], L, L).
revapp([X|L1], L2, L3) :-
    revapp(L1, [X|L2], L3).
```

## ● C++

```
struct link { link *next;
             char elem;
             link(char e): elem(e) {} };
typedef link *list;

list app(list L1, list L2)
{ list L3, *lp = &L3;
  for (list p=L1; p; p=p->next)
  { list newl = new link(p->elem);
    *lp = newl; lp = &newl->next;
  }
  *lp = L2; return L3;
}

list revapp(list L1, list L2)
{ list l = L2;
  for (list p=L1; p; p=p->next)
  { list newl = new link(p->elem);
    newl->next = l; l = newl;
  }
  return l;
}
```

## Generalization of member: select/3 – defined in library lists

```
% select(E, List, Rest): Removing E from List results in list Rest.
select(E, [E|Rest], Rest).      % The head is removed, the tail remains.
select(E, [X|Tail], [X|Rest]) :- % The head remains,
    select(E, Tail, Rest).      % the element is removed from the Tail.
```

## Possible uses:

```
| ?- select(1, [2,1,3,1], L).      % Remove a given element
    L = [2,3,1] ? ; L = [2,1,3] ? ; no
| ?- select(X, [1,2,3], L).      % Remove an arbitrary element
    L=[2,3], X=1 ? ; L=[1,3], X=2 ? ; L=[1,2], X=3 ? ; no
| ?- select(3, L, [1,2]).      % Insert a given element!
    L = [3,1,2] ? ; L = [1,3,2] ? ; L = [1,2,3] ? ; no
| ?- select(3, [2|L], [1,2,7,3,2,1,8,9,4]).
    no % Can one remove 3 from [2|L]
    % to obtain [1,...]?

| ?- select(1, [X,2,X,3], L).
    L = [2,1,3], X = 1 ? ; L = [1,2,3], X = 1 ? ; no
```

- The search space of `select/3` is **finite**, if the 2<sup>nd</sup> or the 3<sup>rd</sup> arg. is closed.

## Permutation of lists – two solutions (ADVANCED)

`perm(+List, ?Perm)`: The list `Perm` is a permutation of `List`

```
perm0([], []).
perm0(L, [H|P]) :-
    select(H, L, R),      % Select H from L as the head of the output, R remaining.
    perm0(R, P).         % Permute R to become P, the tail of the output list.

| ?- perm0([a,b,c], L).
    L = [a,b,c] ? ; L = [a,c,b] ? ; L = [b,a,c] ? ;
    L = [b,c,a] ? ; L = [c,a,b] ? ; L = [c,b,a] ? ; no

perm1([], []).
perm1([H|T], P) :-
    perm1(T, P1),        % Permute T, the tail of the input list, obtaining P1.
    select(H, P, P1).    % Insert H, the head of the input list, into an arbitrary
    % mode: + - +      % position within P1 to obtain the output list, P.

| ?- perm1([a,b,c], L).
    L = [a,b,c] ? ; L = [b,a,c] ? ; L = [b,c,a] ? ;
    L = [a,c,b] ? ; L = [c,a,b] ? ; L = [c,b,a] ? ; no
```

- `perm` is symmetric, so the two predicates have the same meaning (WHAT)
- But the second variant is much faster!

## Contents

## 2 Declarative Programming with Prolog

- Prolog – first steps
- Prolog execution models
- The syntax of the (unsweetened) Prolog language
- Further control constructs
- Operators and special terms
- Working with lists
- Term ordering
- Higher order predicates
- All solutions predicates
- Efficient programming in Prolog
- Executable specifications
- Further reading

## Principles of Prolog term ordering &lt;

Different kinds ordered left-to-right:

var < float < integer <  
< atom < compound

- Ordering of variables: system dependent
- Ordering of floats and integers: usual ( $x < y \Leftrightarrow x < y$ )
- Ordering of atoms: lexicographical ( $abc < abcd$ ,  $abcv < abcz$ )
- Compound terms:  $\text{name}_a(a_1, \dots, a_n) < \text{name}_b(b_1, \dots, b_m)$  iff
  - $n < m$ , e.g.  $p(x, s(u, v, w)) < a(b, c, d)$ , or
  - $n = m$ , and  $\text{name}_a < \text{name}_b$  (lexicographically), e.g.  $a(x, y) < p(b, c)$ , or
  - $n = m$ ,  $\text{name}_a = \text{name}_b$ , and for the first  $i$  where  $a_i \neq b_i$ ,  $a_i < b_i$ , e.g.  $r(1, u+v, 3, x) < r(1, u+v, 5, a)$

## Built-in predicates for comparing Prolog terms

- Comparing two Prolog terms:

| Goal                                     | holds if                                                                 |
|------------------------------------------|--------------------------------------------------------------------------|
| $\text{Term1} == \text{Term2}$           | $\text{Term1} \not< \text{Term2} \wedge \text{Term2} \not< \text{Term1}$ |
| $\text{Term1} \backslash== \text{Term2}$ | $\text{Term1} < \text{Term2} \vee \text{Term2} < \text{Term1}$           |
| $\text{Term1} @< \text{Term2}$           | $\text{Term1} < \text{Term2}$                                            |
| $\text{Term1} @=< \text{Term2}$          | $\text{Term2} \not< \text{Term1}$                                        |
| $\text{Term1} @> \text{Term2}$           | $\text{Term2} < \text{Term1}$                                            |
| $\text{Term1} @>= \text{Term2}$          | $\text{Term1} \not< \text{Term2}$                                        |

- The comparison predicates are not purely logical:
  - $| \text{?- } X @< 3, X = 4. \implies X = 4$
  - $| \text{?- } X = 4, X @< 3. \implies \text{no}$
 as they rely on the **current instantiation** of their arguments
- Comparison uses, of course, the canonical representation:
  - $| \text{?- } [1, 2, 3, 4] @< s(1,2,3). \implies \text{yes}$
- BIP sort(L, S) sorts (using @<) a list L of arbitrary Prolog terms, removing duplicates (w.r.t. ==). Thus the result is a strictly increasing list s.
  - $| \text{?- } \text{sort}([1, 2.0, s(a,b), s(a,c), s, X, s(Y), t(a), s(a), 1, X], L).$   
 $L = [X, 2.0, 1, s, s(Y), s(a), t(a), s(a,b), s(a,c)] ?$

## Equality-like Prolog predicates – a summary

Recall: a Prolog term is *ground* if it contains no unbound variables

- $U = V$ :  $U$  unifies with  $V$   
No errors. May bind vars.
  - $| \text{?- } X = 1+2. \implies X = 1+2$
  - $| \text{?- } 3 = 1+2. \implies \text{no}$
- $U == V$ :  $U$  is identical to  $V$ , i.e.  $U=V$  succeeds with no bindings  
No errors, no bindings.
  - $| \text{?- } X == 1+2. \implies \text{no}$
  - $| \text{?- } 3 == 1+2. \implies \text{no}$
  - $| \text{?- } +(X,Y) == X+Y \implies \text{yes}$
- $U ::= V$ : The value of  $U$  is arithmetically equal to that of  $V$ .  
No bindings. Error if  $U$  or  $V$  is not a (ground) arithmetic expression.
  - $| \text{?- } X ::= 1+2. \implies \text{error}$
  - $| \text{?- } 1+2 ::= X. \implies \text{error}$
  - $| \text{?- } 2+1 ::= 1+2. \implies \text{yes}$
  - $| \text{?- } 3.0 ::= 1+2. \implies \text{yes}$
- $U \text{ is } V$ :  $U$  is unified with the value of  $V$ .  
Error if  $V$  is not a (ground) arithmetic expression.
  - $| \text{?- } X \text{ is } 1+2. \implies X = 3$
  - $| \text{?- } 3.0 \text{ is } 1+2. \implies \text{no}$
  - $| \text{?- } 1+2 \text{ is } X. \implies \text{error}$
  - $| \text{?- } 3 \text{ is } 1+2. \implies \text{yes}$
  - $| \text{?- } 1+2 \text{ is } 1+2. \implies \text{no}$

## Nonequality-like Prolog predicates – a summary

- Nonequality-like Prolog predicates **never** bind variables.
- $U \backslash= V$ :  $U$  does not unify with  $V$ .  
No errors.
  - $| \text{?- } X \backslash= 1+2. \implies \text{no}$
  - $| \text{?- } X \backslash= 1+2, X = 1. \implies \text{no}$
  - $| \text{?- } X = 1, X \backslash= 1+2. \implies \text{yes}$
  - $| \text{?- } +(1,2) \backslash= 1+2. \implies \text{no}$
- $U \backslash== V$ :  $U$  is not identical to  $V$ .  
No errors.
  - $| \text{?- } X \backslash== 1+2. \implies \text{yes}$
  - $| \text{?- } X \backslash== 1+2, X=1+2. \implies \text{yes}$
  - $| \text{?- } 3 \backslash== 1+2. \implies \text{yes}$
  - $| \text{?- } +(1,2) \backslash== 1+2 \implies \text{no}$
- $U \backslash= V$ : The values of the arithmetic expressions  $U$  and  $V$  are different.  
Error if  $U$  or  $V$  is not a (ground) arithmetic expression.
  - $| \text{?- } X \backslash= 1+2. \implies \text{error}$
  - $| \text{?- } 1+2 \backslash= X. \implies \text{error}$
  - $| \text{?- } 2+1 \backslash= 1+2. \implies \text{no}$
  - $| \text{?- } 2.0 \backslash= 1+1. \implies \text{no}$

## (Non)equality-like Prolog predicates – examples

|     |        | Unification |                   | Identical terms |                    | Arithmetic |                   |                   |
|-----|--------|-------------|-------------------|-----------------|--------------------|------------|-------------------|-------------------|
| $U$ | $V$    | $U = V$     | $U \backslash= V$ | $U == V$        | $U \backslash== V$ | $U := V$   | $U \backslash= V$ | $U \text{ is } V$ |
| 1   | 2      | no          | yes               | no              | yes                | no         | yes               | no                |
| a   | b      | no          | yes               | no              | yes                | error      | error             | error             |
| 1+2 | +(1,2) | yes         | no                | yes             | no                 | yes        | no                | no                |
| 1+2 | 2+1    | no          | yes               | no              | yes                | yes        | no                | no                |
| 1+2 | 3      | no          | yes               | no              | yes                | yes        | no                | no                |
| 3   | 1+2    | no          | yes               | no              | yes                | yes        | no                | yes               |
| X   | 1+2    | X=1+2       | no                | no              | yes                | error      | error             | X=3               |
| X   | Y      | X=Y         | no                | no              | yes                | error      | error             | error             |
| X   | X      | yes         | no                | yes             | no                 | error      | error             | error             |

Legend: yes – success; no – failure.

## 2 Declarative Programming with Prolog

- Prolog – first steps
- Prolog execution models
- The syntax of the (unsweetened) Prolog language
- Further control constructs
- Operators and special terms
- Working with lists
- Term ordering
- Higher order predicates
- All solutions predicates
- Efficient programming in Prolog
- Executable specifications
- Further reading

## Higher order programming: using predicates as arguments

- Example: collect all nonzero elements of a list
 

```
% nonzero_elems(Xs, Ys): Ys is a list of all nonzero elements of Xs
nonzero_elems([], []).
nonzero_elems([X|Xs], Ys) :-
    ( 0 \= X -> Ys = [X|Ys1]
    ; Ys = Ys1
    ),
    nonzero_elems(Xs, Ys1).
```
- Generalize to a predicate where the **condition** is given as an argument
 

```
% include(Pred, Xs, Ys): Ys = list of elems of Xs that satisfy Pred
include(_Pred, [], []).
include(Pred, [X|Xs], Ys) :-
    ( call(Pred, X) -> Ys = [X|Ys1]
    ; Ys = Ys1
    ),
    include(Pred, Xs, Ys1).
```
- Specialize `include` for collecting nonzero elements:
 

```
nonz(X) :- 0 \= X.
nonzero_elems(L, L1) :- include(nonz, L, L1).
```

## Higher order predicates

- A higher order predicate (or meta-predicate) is a predicate with an argument which is interpreted as a goal, or a *partial goal*
- A **partial goal** is a goal with the last few arguments missing
  - e.g., a predicate name is a partial goal (hence variable name `Pred` is often used for partial goals)
- The BIP `call(PG, X)`, where `PG` is a partial goal, adds `X` as the last argument to `PG` and executes this new goal:
  - if `PG` is an atom  $\Rightarrow$  it calls `PG(X)`, e.g. `call(number, X)  $\equiv$  number(X)`
  - if `PG` is a compound `Pred(A1, ..., An)`  $\Rightarrow$  it calls `Pred(A1, ..., An, X)`, e.g. `call(\=(0), X)  $\equiv$  \=(0,X)  $\equiv$  0 \= X`
- Predicate `include(Pred, L, FL)` is in library(`lists`)
 

```
| ?- L=[1,2,a,X,b,0,3+4],
    include(number, L, Nums). % Nums = { X  $\in$  L | number(X) }
Nums = [1,2,0] ? ; no
| ?- L=[0,2,0,3,-1,0],
    include(\=(0), L, NZs). % NZs = { X  $\in$  L | \=(0,X) }
NZs = [2,3,-1] ?
```

## Calling predicates with additional arguments

- Recall: a **callable term** is a compound or atom.
- There is a group of built-in predicates `call/N`
  - `call(Goal)`: invokes `Goal`, where `Goal` is a callable term
  - `call(PG, A)`: Adds `A` as the **last** argument to `PG`, and invokes it.
  - `call(PG, A, B)`: Adds `A` and `B` as the **last two** args to `PG`, invokes it.
  - `call(PG, A1, ..., An)`: Adds `A1, ..., An` as the **last *n*** arguments to `PG`, and invokes the goal so obtained.

- `PG` is a **partial goal**, to be extended with additional arguments before calling. It has to be a callable term.

```
even(X) :- X mod 2 =:= 0.
```

```
| ?- include(even, [1,3,2,9,6,4,0], FL).
           => FL = [2,6,4,0] ; no
```

```
divisible_by(N, X) :- X mod N =:= 0.
```

```
| ?- include(divisible_by(3), [1,3,2,9,6,4,0], FL).
           => FL = [3,9,6,0] ; no
```

- In descriptions we often abbreviate `call(PG, A1, ..., An)` to `PG(A1, ..., An)`

## An important higher order predicate: `maplist/3`

- `maplist(:PG, ?L, ?ML)`: for each `x` element of `L` and the **corresponding** `y` element of `ML`, `call(PG, X, Y)` holds, where `PG` is a partial goal requiring two additional arguments
- Annotation “:” (as in `:PG` above) marks a **meta** argument, i.e. a term to be interpreted as a goal or a partial goal

```
maplist(_PG, [], []).
maplist(PG, [X|Xs], [Y|Ys]) :-
    call(PG, X, Y),
    maplist(PG, Xs, Ys).
```

```
| ?- maplist(reverse, [[1,2],[3,4]], LL). => LL = [[2,1],[4,3]] ? ; no
```

```
square(X, Y) :- Y is X*X.
```

```
mult(N, X, NX) :- NX is N*X.
```

```
| ?- maplist(square, [1,2,3,4], L). => L = [1,4,9,16] ? ; no
```

```
| ?- maplist(mult(2), [1,2,3,4], L). => L = [2,4,6,8] ? ; no
```

```
| ?- maplist(mult(-5), [1,2,3], L). => L = [-5,-10,-15] ? ; no
```

## Variants of `maplist`

In SICStus, `maplist` can also be used with 2 and 4 arguments

- `maplist(:Pred, +Xs)` is true if for each `x` element of `Xs`, `Pred(x)` holds.

- Example: check if a condition holds for all elements of a list

```
all_positive(Xs) :-
    maplist(<(0), Xs).
    % all elements of Xs are positive
    % ∀ X ∈ Xs, <(0, X), i.e. 0 < X holds
```

- `maplist(:Pred, ?Xs, ?Ys, ?Zs)` is true when `Xs`, `Ys`, and `Zs` are lists of equal length, and `Pred(X, Y, Z)` is true for corresponding elements `x` of `Xs`, `y` of `Ys`, and `z` of `Zs`. At least one of `Xs`, `Ys`, `Zs` has to be a closed list.

- Example: add two vectors

```
add_vectors(VA, VB, VC) :-
    maplist(plus, VA, VB, VC).
    plus(A, B, C) :- C is A+B.
| ?- add_vectors([10,20,30], [3,2,1], V). => V = [13,22,31] ? ; no
```

- The implementation of `maplist/4` (easy to generalize :-):

```
maplist(_PG, [], [], []).
maplist(PG, [X|Xs], [Y|Ys], [Z|Zs]) :-
    call(PG, X, Y, Z), maplist(PG, Xs, Ys, Zs).
```

## Another important higher order predicate: `scanlist (SWI: foldl)`

- Example:
 

```
plus(A, S0, S) :- S is S0+A.
| ?- scanlist(plus, [1,3,5], 0, Sum). => Sum = 9 ? ; no
    % 0+1+3+5 = 9
```

This executes as: `plus(0, 1, S1)`, `plus(S1, 3, S2)`, `plus(S2, 5, Sum)`.

- In general: `scanlist(acc, [E1, E2, ..., En], S0, Sn)` is expanded as:

```
acc(S0, E1, S1), acc(S1, E2, S2), ..., acc(Sn-1, En, Sn)
```

- `scanlist(:PG, ?L, ?Init, ?Final)`:

- `PG` represents the above accumulating predicate `acc`
- `scanlist` applies the `acc` predicate repeatedly, on all elements of list `L`, left-to-right, where `Init = S0` and `Final = Sn`.

- For processing two lists (of the same length), use `scanlist/5`, e.g.

```
prodsum(A, B, PS0, PS) :- PS is PS0 + A*B.
```

```
scalar_product(As, Bs, SP) :- scanlist(prodsum, As, Bs, 0, SP).
```

```
| ?- scalar_product([1,0,2], [3,4,5], SP). => SP = 13 ? ; no
```

- In SICStus, there is also a `scanlist/6` predicate, for processing 3 lists

## Contents

## 2 Declarative Programming with Prolog

- Prolog – first steps
- Prolog execution models
- The syntax of the (unsweetened) Prolog language
- Further control constructs
- Operators and special terms
- Working with lists
- Term ordering
- Higher order predicates
- All solutions predicates
- Efficient programming in Prolog
- Executable specifications
- Further reading

## All solutions built-in predicates – introduction

- All solution BIPs are higher order predicates analogous to list comprehensions in Haskell, Python, etc.
- There are three such predicates: `findall/3` (the simplest), `bagof/3` and `setof/3`; having the same arguments, but somewhat different behavior

- Examples for `findall/3`:

```
| ?- findall(X, (member(X, [1,7,8,3,2,4]), X > 3), L).
%      {X |      X ∈ {1,7,8,3,2,4}, X > 3} = L
      ⇒ L = [7,8,4] ? ; no
| ?- findall(X, (member(X, [1,7,8,3,2,4]), X > 8), L).
%      {X |      X ∈ {1,7,8,3,2,4}, X > 8} = L
      ⇒ L = [] ? ; no
| ?- findall(X-Y, (between(1, 3, X), between(1, X, Y)), L).
%      {X-Y |      1 ≤ X ≤ 3,      1 ≤ Y ≤ X} = L
      ⇒ L = [1-1,2-1,2-2,3-1,3-2,3-3] ? ; no
```

Recall: `between(+N, +M, ?X)` enumerates in `X` the integers `N, N+1, ..., M`. In SICStus, it requires loading `library(between)`.

Finding all solutions: the BIP `findall(?Temp1, :Goal, ?L)`

Approximate meaning: `L` is a list of `Temp1` terms for each solution of `Goal`

The execution of the BIP `findall/3` (procedural semantics):

- Interpret term `Goal` as a goal, and call it
- For each solution of `Goal`:
  - store a *copy* of `Temp1` (`copy`  $\implies$  replace vars in `Temp1` by new ones)  
Note that copying requires time proportional to the size of `Temp1`
  - continue with failure (to enumerate further solutions)
- When there are no more solutions (`Goal` fails)
  - collect the stored `Temp1` values into a list, unify it with `L`.
- When a solution contains (possibly multiple instances of) a variable (e.g. `A`), then each of these will be replaced by a single new variable (e.g. `_A`):  

```
| ?- findall(T, member(T, [A-A,B-B,A]), L).
      ⇒ L= [_A-_A,_B-_B,_C] ? ; no
```

All solutions: the BIP `bagof(?Temp1, :Goal, ?L)`

- Exactly the same arguments as in `findall/3`.  
`bagof/3` is the same as `findall/3`, except when there are unbound variables in `Goal` which do not occur in `Temp1` (so called **free** variables)  

```
% emp(Er, Ee): employer Er employs employee Ee.
emp(a,b). emp(a,c). emp(b,c). emp(b,d).
| ?- findall(E, emp(R, E), Es). % Es ≡ the list of all employees
      ⇒ Es = [b,c,c,d] ? ; no i.e. Es = {E | ∃ R. (R employs E)}
```
- `bagof` does not treat free vars as existentially quantified. Instead it **enumerates** all possible values for the free vars (all employers) and for each such choice it builds a separate list of solutions:  

```
| ?- bagof(E, emp(R, E), Es). % Es ≡ list of Es employed by any possible R.
      ⇒ R = a, Es = [b,c] ? ;
      ⇒ R = b, Es = [c,d] ? ; no
```
- Use operator `^` to achieve existential quantification in `bagof`:  

```
| ?- bagof(E, R^emp(R, E), Es). % Collect Es for which ∃R. emp(R, E)
      ⇒ Es = [b,c,c,d] ? ; no
```
- `bagof` preserves variables (but it is slower than `findall :-()`):  

```
| ?- bagof(T, member(T, [A-A,B-B,A]), L). ⇒ L = [A-A,B-B,A] ? ; no
```

All solutions: the BIP `setof/3`

- `setof(?Templ, :Goal, ?List)`
- The execution of the procedure:
  - same as: `bagof(Templ, Goal, L0), sort(L0, List)`
  - recall: `sort(+L, ?SL)` is a built-in predicate which sorts `L` using the `@<` built-in predicate removes duplicates and unifies the result with `SL`
- Example:
 

```
graph([a-b,a-c,b-c,c-d,b-d]).
% Graph has a node V.
has_node(Graph, V) :- member(A-B, Graph), ( V = A ; V = B ).
% The set of nodes of G is Vs.
graph_nodes(G, Vs) :- setof(V, has_node(G, V), Vs).
| ?- graph(_G), graph_nodes(_G, Vs). => Vs = [a,b,c,d] ? ; no
```

  - The syntax of the (unsweetened) Prolog language
  - Further control constructs
  - Operators and special terms
  - Working with lists
  - Term ordering
  - Higher order predicates
  - All solutions predicates
  - Efficient programming in Prolog
  - Executable specifications
  - Further reading

## Causes of inefficiency – preview

- **Unnecessary choice points** (ChPs) waste both time and space  
Recursive definitions often leave choice points behind on exit, e.g.:
  - `% fact0(+N, ?F): F = N!`  
`fact0(0, 1).`  
`fact0(N, F) :- N > 0, N1 is N-1, fact0(N1, F1), F is N*F1.`
  - Remedy: use **if-then-else** or the **cut** BIP (coming soon)
  - `% last0(L, E): The last element of L is E.`  
`last0([E], E).`  
`last0(_|L], E) :- last0(L, E).`
  - Remedy: rewrite to make use of **indexing** (or cut, or if-then-else)
- **General recursion**, as opposed to tail recursion  
As an example, see the `fact0/2` predicate above  
Remedy: re-formulate to a **tail recursive** form, using **accumulators**

## The cut – the BIP underlying if-then-else and negation

- The cut, denoted by `!`, is a BIP with no arguments, i.e. its functor is `!/0`.
- Execution: the cut always succeeds with these two side effects:
  - **Restrict to the first solution of a goal:**  
Remove all choice points created within the goal(s) preceding the `!`.  
`% is_a_parent(+P): check if a given P is a parent.`  
`is_a_parent(P) :- has_parent(_, P), !.`
  - **Commit to the clause containing the cut:**  
Remove the choice of any further clauses in the current predicate.  
`fact1(0, F) :- !, F = 1. % Assign output vars only after the cut,`  
`% both for correctness and efficiency`  
`fact1(N, F) :- N > 0, N1 is N-1, fact1(N1, F1), F is N*F1.`
- Definition: if `q :- ..., p, ...` then the **parent goal** of `p` is the goal matching the clause head `q`
- Effects of cut in the search tree: removes all choice points up to and including the node labelled with the **parent goal of the cut**.
- In the procedure box model: Fail port of cut  $\implies$  Fail port of parent goal

## How does “cut” prune the search tree – an example

```

a(X, Y) :- b(X), c(X, Y).
a(X, Y) :- d(X, Y).

c(s(X), Y) :- Y is X+10.
c(s(X), Y) :- Y is X+20.

a_cut(X, Y) :- b(X), !, c(X, Y).
a_cut(X, Y) :- d(X, Y).

test(Pred, X, Res) :-
    findall(X-Y, call(Pred, X, Y), Res).

```

### Sample runs:

```

| ?- test(a, s(_), Res). => Res = [s(1)-11,s(1)-21,s(2)-12,
                                s(2)-22,s(3)-30] ?
| ?- test(a, t(_), Res). => Res = [t(4)-40] ?
| ?- test(a_cut, s(_), Res). => Res = [s(1)-11,s(1)-21] ?
| ?- test(a_cut, s(3), Res). => Res = [s(3)-30] ?
| ?- test(a_cut, t(_), Res). => Res = [t(4)-40] ?

```

## Avoid leaving unnecessary choice points

- Add a cut if you know that remaining branches are doomed to fail. (These are so called **green cuts**, which do not remove solutions.)
- Example of a green cut:

```

% last1(L, E): The last element of L is E.
last1([E], E) :- !.
last1(_|L, E) :- last1(L, E).

```

In the absence of the cut, the goal `last1([1], X)` will return the answer `X = 1`, and leave a choice point. When this choice point is explored `last1([], X)` will be called which will always fail.

- Instead of a cut, one can use if-then-else:

```

last2([E|L], X) :- ( L == [] -> X = E
                    ; last2(L, X)
                    ).

fact2(N, F) :- ( N == 0 -> F = 1
                ; N > 0, N1 is N-1, fact2(N1, F1), F is N*F1
                ).

```

## Avoid leaving unnecessary choice points – indexing

- Recall a simple example predicate, summing a binary tree:

```

% tree_sum(+Tree, ?Sum):
% Sum is the sum of integers in the leaves of Tree.
tree_sum(leaf(Value), Value).      1st head arg's functor: leaf/1
tree_sum(node(Left, Right), S) :- 1st head arg's functor: node/2
    tree_sum(Left, S1), tree_sum(Right, S2), S is S1+S2.

```

- Indexing groups the clauses of a predicate based on the outermost functor of (usually) the first argument.
- The compiler generates code (using hashing) to select the subset of clauses that corresponds to this outermost functor.
- If the subset contains a single clause, no choicepoint is created. (This is the case in the above example.)

## SICStus specific: avoid choice points in if-then-else (ADVANCED)

- Consider an if-then-else goal of the form: `( cond -> then ; else )`.
- Before `cond`, a ChP is normally created (removed at `->` or before `else`).
- In **SICStus Prolog** no choice points are created, if `cond` only contains:
  - arithmetical comparisons (e.g., `<`, `=<`, `=:=`); and/or
  - built-in predicates checking the term type (e.g., `atom`, `number`); and/or
  - general comparison operators (e.g., `@<`, `@=<`, `==`).
- Analogously, no ChPs are made for `head :- cond, !, then.`, if all arguments of `head` are distinct variables, and `cond` is just like above.
- Further improved variants of `fact2` and `last2` with no ChPs created:

```

fact3(N, F) :- ( N == 0 -> F = 1      % used to be N = 0
                ; N > 0, N1 is N-1, fact(N1, F1), F is N*F1
                ).

last3([E|L], X) :- ( L == [] -> X = E      % used to be L = []
                    ; last3(L, X)
                    ).

```

## Indexing – an introductory example

- A sample (meaningless) program to illustrate indexing.

```
p(0, a).      /* (1) */      q(1).
p(X, t) :- q(X). /* (2) */      q(2).
p(s(0), b).   /* (3) */
p(s(1), c).   /* (4) */
p(9, z).      /* (5) */
```

- For the call `p(A, B)`, the **compiler** produces a **case statement**-like construct, to determine the list of applicable clauses:

```
(VAR)   if A is a variable:      (1) (2) (3) (4) (5)
(0/0)   if A = 0 (A's main functor is 0/0): (1) (2)
(s/1)   if A's main functor is s/1:      (2) (3) (4)
(9/0)   if A = 9:                (2) (5)
(OTHER) in all other cases:      (2)
```

- Example calls (do they create and leave a choice point?)
  - `p(1, Y)` takes branch **(OTHER)**, does not create a choice point.
  - `p(s(1), Y)` takes branch **(s/1)**, creates a choice point, but removes it and exits without leaving a choice point.
  - `p(s(0), Y)` takes branch **(s/1)**, and exits leaving a choice point.

## Indexing

- Indexing improves the efficiency of Prolog execution by
  - speeding up the selection of clauses matching a particular call;
  - using a **compile-time** grouping of the clauses of the predicate.
- Most Prolog systems, including SICStus, use only the main (i.e. outermost) functor of the **first** argument for indexing, which is
  - `C/0`, if the argument is a constant (atom or number) `C`;
  - `R/N`, if the argument is a compound with name `R` and arity `N`;
  - undefined, if the argument is a variable.

### Implementing indexing

- Compile-time: collect the set of (outermost) functors of nonvar terms occurring as first args, build the **case statement** (see prev. slide)
- Run-time: select the relevant clause list using the first arg. of the call. This is practically a constant time operation, as it uses **hashing**.
  - If the clause list is a singleton, **no choice point** is created.
  - Otherwise a choice point **is** created, which will be removed before entering the **last** branch.

## Getting the most out of indexing

- Get deep indexing through helper predicates (rewrite `p/2` to `q/2`):

```
p(0, a).      q(0, a).
p(s(0), b).   q(s(X), Y) :-
p(s(1), c).   q_aux(X, Y).
p(9, z).      q(9, z).
```

Pred. `q(X, Y)` will not create choice points if `x` is ground.

- Indexing does not deal with arithmetic comparisons
  - E.g., `N = 0` and `N > 0` are not recognized as mutually exclusive.
- Indexing and lists
  - Putting the (input) list in the first argument makes indexing work.
  - Indexing distinguishes between `[]` and `[...|...]` (resp. functors: `'[]'/0` and `'.'/2`).
  - For proper lists, the order of the two clauses is not relevant
  - For use with open ended lists: put the clause for `[]` first, to avoid an infinite loop (an infinite choice may still remain)

## Indexing list handling predicates

- Predicate `app/3` creates no choice points if the first argument is a proper list:

```
% app(L1, L2, L3): L1 ⊕ L2 = L3.           % 1st arg funct:
app([], L, L).                             % []/0
app([X|L1], L2, [X|L3]) :-                 % . /2
    app(L1, L2, L3).
```

- The same is true for `revapp/3`:

```
% revapp(L1, L2, L3):
% appending the reverse of L1 and L2 gives L3
revapp([], L, L).                           % []/0
revapp([X|L1], L2, L3) :-                   % . /2
    revapp(L1, [X|L2], L3).
```

## Indexing list handling predicates, cont'd

- Getting the last element of a list: `last0/2` leaves a choice point.

```
% last0(L, E): The last element of L is E.
last0([H], H).                               % . /2
last0([_|T], E) :- last0(T, E).               % . /2
```

- The variant `last4/2` uses a helper predicate, creates no choice points:

```
last4([H|T], E) :- last4(T, H, E).             (*)
% last4(T, H, E): The last element of [H|T] is E.
last4([], E, E).                               % []/0
last4([H|T], _, E) :- last4(T, H, E).         % . /2
```

- `member0/2` (as defined earlier) always leaves a choice point.

```
% member0(E, L): E is an element of L.
member0(E, [E|_]).                             % VAR
member0(E, [_|T]) :- member0(E, T).             % VAR
```

- Write the head comment and the clauses of `member1/3`, so that `member1/2` leaves no choice point when the last element of a (proper) list is returned.

```
member1(E, [H|T]) :- member1(T, H, E).         % cf. (*)
% member1(T, H, E): ...
```

## Tail recursion

- In general, recursion is expensive both in terms of time and space.
- The special case of **tail recursion** can be compiled to a loop. Conditions:
  - the recursive call is the last to be executed in the clause body, i.e.:
    - it is textually the last subgoal in the body; or
    - the last subgoal is a disjunction/if-then-else, and the recursive call is the last in one of the branches
  - no ChPs left in the predicate when the recursive call is reached

- Example

```
% all_pos(+L): all elements of number list L are positive.
all_pos([]).
all_pos([X|L]) :-
    X > 0, all_pos(L).
```

- Tail recursion optimization, TRO:** the memory allocated by the clause is freed **before** the last call is executed.
- This optimization is performed not only for recursive calls but for the **last** calls in general (**last call optimization, LCO**).

## Making a predicate tail recursive – accumulators

- Example: the sum of a list of numbers. The left recursive variant:

```
% sum0(+List, -Sum): the sum of the elements of List is Sum.
sum0([], 0).
sum0([X|L], Sum) :- sum0(L, Sum0), Sum is Sum0+X.
```

Note that  $\text{sum0}([a_1, \dots, a_n], S) \implies S = 0 + a_n + \dots + a_1$  (right to left)

- For TRO, define a helper pred, with an arg. storing the “sum so far”:

```
% sum(+List, +Sum0, -Sum):
% (Σ List) + Sum0 = Sum, i.e. Σ List = Sum - Sum0.
sum([], Sum, Sum).
sum([X|L], Sum0, Sum) :-
    Sum1 is Sum0+X,      % Increment the ‘sum so far’
    sum(L, Sum1, Sum).  % recurse with the tail and the new sum so far
```

- Arguments `Sum0` and `Sum` form an **accumulator pair**: `Sum0` is an intermediate while `Sum` is the final value of the accumulator.

The initial value is supplied when defining `sum/2`:

```
% sumlist(+List, ?Sum): Σ List = Sum. Available from library(lists).
sumlist(List, Sum) :- sum(List, 0, Sum).
```

Note that  $\text{sumlist}([a_1, \dots, a_n], S) \implies S = 0 + a_1 + \dots + a_n$  (left to right)

## Accumulators – making factorial tail-recursive

- Two arguments of a pred. forming an **accumulator pair**: the declarative equivalent of the imperative variable (i.e. a variable with a mutable state)
- The two parts: the state of the mutable quantity at pred. entry and exit.
- Example: making factorial tail-recursive. The mid-recursive version:

```
% fact0(N, F): F = N!.
fact0(N, F) :- ( N == 0 -> F = 1
                ; N > 0, N1 is N-1, fact0(N1, F1), F is F1*N1
                ).
```

| ?- fact0(4, F).  $\implies F = 24 \sim 1*1*2*3*4$

- Helper predicate: `fact(N, F0, F)`, `F0` is the product accumulated so far.

```
% fact(N, F0, F): F = F0*N!.
fact(N, F0, F) :- ( N == 0 -> F = F0
                   ; N > 0, F1 is F0*N, N1 is N-1, fact(N1, F1, F)
                   ).
```

```
fact(N, F) :-
    fact(N, 1, F).
```

| ?- fact(4, F).  $\implies F = 24 \sim 1*4*3*2*1$

## Accumulating lists – higher order approaches (ADVANCED)

- Recap predicate `revapp/3`:  

```
% revapp(L, RO, R): The reverse of L prepended to RO gives R.
revapp0([], RO, R) :- R = RO.
revapp0([X|L], RO, R) :- R1 = [X|RO], revapp0(L, R1, R).
```
- Introduce the list construction predicate `cons/3`  

```
% L1 is a list constructed from the head X and tail L0.
cons(X, L0, L1) :- L1 = [X|L0].
revapp1([], RO, R) :- R = RO.
revapp1([X|L], RO, R) :- cons(X, RO, R1), revapp1(L, R1, R).
```
- A higher order (HO) solution (in SWI use `foldl` instead of `scanlist`):  

```
revapp2(L, RO, R) :- scanlist(cons, L, RO, R).
```
- Summing a list, HO solution (`% sum2(L, Sum): list L sums to Sum.`)  

```
plus(X, S0, S1) :- S1 is S0+X.
sum2(L, Sum) :- scanlist(plus, L, 0, Sum).
```
- (ADV<sup>2</sup>) Appending lists, HO sol. (`% app(L1, L2, L): L1 ⊕ L2 = L.`)  

```
% decomp(X, C, B): List C can be decomposed to head X and tail B
decomp(X, C, B) :- C = [X|B].
app(A, B, C) :- scanlist(decomp, A, C, B).
```

## Accumulating lists – avoiding append

- Example: calculate the list of leaf values of a tree. Without accumulators:  

```
% tree_list0(+T, ?L): L is the list of the leaf values of tree T.
tree_list0(leaf(Value), [Value]).
tree_list0(node(Left, Right), L) :-
    tree_list0(Left, L1), tree_list0(Right, L2), append(L1, L2, L).
```
- Building the list of tree leaves using accumulators:  

```
tree_list(Tree, L) :-
    tree_list(Tree, [], L). % Initialize the list accumulator to []

% tree_list(+Tree, +L0, L): The list of the
% leaf values of Tree prepended to L0 is L.
tree_list(leaf(Value), L0, L) :- L = [Value|L0].
tree_list(node(Left, Right), L0, L) :-
    tree_list(Right, L0, L1), tree_list(Left, L1, L).

! ?- tree_list(node(node(leaf(a),leaf(b)),leaf(c)), L). => L = [a,b,c]? ; no
```
- Note that one of the two recursive calls is tail-recursive.
- Also, there is no need to append the intermediate lists!

## Accumulators for implementing imperative (mutable) variables

- Let  $L = [x_1, \dots, x_n]$  be a number list.  $x_i$  is *left-visible* in  $L$ , iff  $\forall j < i. (x_j < x_i)$
- Determine the count of left-visible elements in a list of **positive** integers:

### Imperative, C-like algorithm

```
int viscnt(list L) {
    int MV = 0; // max visible
    int VC = 0; // visible cnt

loop:
    if (empty(L)) return VC;

    { int H = hd(L), L = tl(L);
      if (H > MV)
          { VC += 1; MV = H; }
      // else VC, MV unchanged
    }
    goto loop;
}
```

### Prolog code

```
% List L has VC left-visible elements.
viscnt(L, VC) :- viscnt(L,
                        0,
                        0, VC).

% viscnt(L, MV, VCO, VC): L has VC-VCO
% left-visible elements which are > MV.
viscnt([], _, VCO, VC) :- VC = VCO.
viscnt(L0, MV0, VCO, VC) :- % (1)
    L0 = [H|L1],
    ( H > MV0
    -> VC1 is VCO+1, MV1 = H
    ; VC1 = VCO, MV1 = MV0 % (2)
    ),
    viscnt(L1, MV1, VC1, VC). % (3)
```

## Mapping a C loop to a Prolog predicate

- Each C variable initialized before the loop and used in it becomes an input argument of the Prolog predicate
- Each C variable assigned to in the loop and used afterwards becomes an output argument of the Prolog predicate
- Each **occurrence** of a C variable is mapped to a Prolog variable, whenever the variable is assigned, a new Prolog variable is needed, e.g. `MV` is mapped to `MV0, MV1, ...`:
  - The initial values (`L0, MV0, ...`) are the args of the clause head<sup>2</sup> (1)
  - If a branch of if-then(-else) changes a variable, while others don't, then the Prolog code of latter branches has to state that the new Prolog variable is equal to the old one, (2)
  - At the end of the loop the Prolog predicate is called with arguments corresponding to the current values of the C variables, (3)

<sup>2</sup>References of the form (n) point to the previous slide.

## 2 Declarative Programming with Prolog

- Prolog – first steps
- Prolog execution models
- The syntax of the (unsweetened) Prolog language
- Further control constructs
- Operators and special terms
- Working with lists
- Term ordering
- Higher order predicates
- All solutions predicates
- Efficient programming in Prolog
- Executable specifications
- Further reading

## Executable specifications – what are they?

- An executable specification is a piece of **non-recursive** Prolog code which is in a one-to-one correspondence with its **specification**
- Example 1: Finding a contiguous sublist with a given sum

```
% sublist_sum(+L, +Sum, ?SubL): SubL is a sublist of L summing to Sum.
| ?- sublist_sum([1,2,3], 3, SL). => SL = [1,2] ? ; SL = [3] ? ; no
:- use_module(library(lists)). % To import sublist/2, append/2
sublist_sum(L, Sum, SubL) :-
    append([_,SubL,_], L), % SubL is a sublist of L
    sublist(SubL, Sum). % Σ SubL = Sum
```

- Example 2: Finding elements occurring in pairs

```
% paired(+List, ?E, ?I): E is an element of List equal to its
% right neighbour, occurring at (zero-based) index I.
| ?- paired([a,b,b,c,d,d], E, I). => E = b, I = 1 ? ;
=> E = d, I = 4 ? ; no

paired(L, E, I) :-
    append(Pref, [E,E|_], L), % L starts with a sublist Pref,
                                % followed by two elements equal to E
    length(Pref, I). % The length of Pref is I
```

## Executable specification examples: plateau

- A list is a **plateau**, if its length is  $\geq 2$ , and all its elements are the same. (Think of list elements as elevation values.)  
We assume that the list is ground (contains no variables). (\*)
- Example 3: Checking if a list is a plateau. Four variants:  $N = 1, 2, 3, 4$ 
  - ① Use boring/2 (slide 96): `plateau1([A,A|P1], A) :- boring(P1, A).`
  - ② Use maplist/2: `plateau2([A,A|P1], A) :- maplist(=(A), P1).`
  - ③ Use (double) negation: P1 has no element that differs from A  
`plateau3([A,A|P1], A) :- \+ ( member(X, P1), \+ X = A ).`
  - ④ Use the forall/2 library predicate (library(aggregate) in SICStus)  
`plateau4([A,A|P1], A) :- forall( member(X, P1), X = A ).`
- forall(P, Q) succeeds iff Q holds for each solution of P, defined as:  
`forall(P, Q) :- \+ (P, \+ Q). % There is no solution of P for which Q fails.`
- **IMPORTANT:** Because of `\+`, forall/2 will never instantiate vars, cf. (\*)  
| ?- length(L, 4), plateau2(L, 8). L = [8,8,8,8] ? ; no  
| ?- length(L, 4), plateau4(L, 8). L = [8,8,\_A,\_B] ? ; no

## Executable specification examples: the longest plateau prefix

- The maximal plateau prefix (MPP for short) of a list is its longest prefix that is a plateau. E.g. the MPP of [1,1,1,2,1] is [1,1,1].
  - Example 4: Given a list, obtain the length and the repeating element of its MPP. Fail if the list has no MPP (e.g. [3,1,1,1,2,1] has no MPP).  
`% mpp(+L, ?Len, ?A): List L has an MPP of length Len, composed of A's`
  - Let's use append/3 to split L into a P1 plateau prefix and Suff suffix:  
`append(P1, Suff, L), plateauN(P1, A), <check P1 is maximal>`
  - P1 is maximal, if Suff = [] or the head of Suff is not A:  
( Suff = [] -> true ; Suff = [X|\_], X \= A )
  - This can be simplified to: `\+ Suff = [A|_]` (it does not hold that the head of Suff is A)
- ```
mp(L, Len, A) :- % L has an MPP of length Len, composed of A's if
    P1 = [A,A|_], % P1's first two elems are the same, call them A
    append(P1, Suff, L), % P1 ⊕ Suff = L, P1 is a prefix of L followed by Suff
    forall(member(X,P1), % For each X element of P1
           X = A), % X is equal to A *** P1 is a plateau!
    \+ Suff = [A|_], % Suff does not start with A *** P1 is maximal!
    length(P1, Len). % The length of P1 is Len
```

## Executable specification examples: maximal plateau sublist

- A contiguous sublist of a list is a **maximal plateau** sublist, if it is a **plateau that cannot be extended** neither leftwards nor rightwards
- Example 5: enumerate all maximal plateau sublists of a given list

```
% plateau(+L, ?I, ?Len, ?A): List L has a maximal plateau sublist that starts
% at (0-based) index I, has length Len, and is composed of A-s
```

```
| ?- plateau([1,1,1,2,1,4,4,3,7,7,7], I, Len, A).
I = 0, Len = 3, A = 1 ? ;
I = 5, Len = 2, A = 4 ? ;
I = 8, Len = 3, A = 7 ? ; no

plateau(L, I, Len, A) :-
    Pl = [A,A|_],                % The first two elements of Pl are equal,
                                % call them A
    append([Pref,Pl,Suff], L),   % Split L to Pref⊕Pl⊕Suff
    forall( member(X, Pl), X=A ), % For each X element of Pl, X = A holds
    \+ Suff = [A|_],            % Suff does not start with A
    \+ last(Pref, A),           % Pref does not end with A
    length(Pl, Len),            % The length of Pl is Len
    length(Pref, I).            % The length of Pref is I
```

## Building and decomposing compounds: the *univ* predicate

- BIP `=.. /2` (pronounce *univ*) is a standard op. (`xfx`, 700; just as `=`, ...)
- Term `=.. List` holds if
  - Term = *Fun*(*A*<sub>1</sub>, ..., *A*<sub>*n*</sub>) and List = [*Fun*,*A*<sub>1</sub>,..., *A*<sub>*n*</sub>], where *Fun* is an atom and *A*<sub>1</sub>,..., *A*<sub>*n*</sub> are arbitrary terms; or
  - Term = *C* and List = [*C*], where *C* is a constant. (Constants are viewed as compounds with 0 arguments.)
- Whenever you would like to use a var. as a compound name, use *univ*: `X = F(A1,...,An)` causes **syntax error**, use `X =.. [F,A1,...,An]` instead
- Call patterns for *univ*:
  - `+Term =.. ?List` decomposes Term
  - `-Term =.. +List` constructs Term

### Examples

```
| ?- edge(a,b,10) =.. L.      => L = [edge,a,b,10]
| ?- Term =.. [edge,a,b,10]. => Term = edge(a,b,10)
| ?- apple =.. L.           => L = [apple]
| ?- Term =.. [1234].       => Term = 1234
| ?- Term =.. L.           => error
| ?- f(a,g(10,20)) =.. L.   => L = [f,a,g(10,20)]
| ?- Term =.. [/,X,2+X].    => Term = X/(2+X)
```

## Error handling in Prolog

- A BIP for catching exceptions (errors): `catch(:Goal, ?ETerm, :EGoal):`
- Recall: “:” marks a **meta** argument, i.e. a term which is a goal
- BIP `catch/3` runs `Goal`
  - If no exception is raised (no error occurs) during the execution of `Goal`, `catch` ignores the remaining arguments
  - When an exception occurs, an exception term `E` is produced, which contains the details of the exception
    - If `E` unifies with the 2nd argument of `catch`, `ETerm`, it runs `EGoal`
    - Otherwise `catch` propagates the exception further outwards, giving a chance to surrounding `catch` goals
    - If the user code does not “catch” the exception, it is caught by the top level, displaying the error term in a readable form.

```
| ?- X is Y+1.
! Instantiation error in argument 2 of (is)/2
! goal:  _177 is _183+1
| ?- catch(X is Y+1, E, true).
E = error(instantiation_error,instantiation_error(_A is _B+1,2)) ? ; no
| ?- catch(X is Y+1, _, fail).
no
```

## An interesting Prolog task

- A job interview question: construct an arithmetic expression containing integers 1, 3, 4, 6 each exactly once, using the four basic arithmetic operators +, -, \*, /, 0 or more times, so that the expression evaluates to 24
- Let's write a Prolog program for solving this task:

```
:- use_module(library(lists), [permutation/2]).

% arith_expr(+L, +OpL, +Val, -Expr) :
% Expr is an arithmetic expression containing only operators present
% in the list OpL (operators may be used 0 or more times) and
% integers given in list L (each integer has to appear exactly once),
% so that the value of the expression is Val.
arith_expr(L, OpL, Val, Expr) :-
    permutation(L, PL),                % permute the list of integers into PL
    leaves_ops_expr(PL, OpL, Expr),    % build Expr with PL as the leaves-list
    catch(Expr := Val, _, fail).      % check if Expr evaluates to Val, fail
                                     % if there is a division-by-0 error.
```

## An interesting Prolog task, cont'd

```
% leaves_ops_expr(+L, +OpL, ?Expr): Expr is an arithmetic expression
% which uses operators from OpL (0 or more times each) whose leaves,
% read left-to-right, form the list L.
leaves_ops_expr(L, _OpL, Expr) :-
    L = [Expr].                % If L is a singleton, Expr is the only element
leaves_ops_expr(L, OpL, Expr) :-
    append(L1, L2, L),         % Split L to nonempty L1 and L2,
    L1 \= [], L2 \= [],
    leaves_ops_expr(L1, OpL, E1), % generate E1 from L1 (using OpL),
    leaves_ops_expr(L2, OpL, E2), % generate E2 from L2 (using OpL),
    member(Op, OpL),           % choose an operator Op from OpL,
    Expr =.. [Op,E1,E2].       % build the expression 'E1 Op E2'

| ?- solve(66).
(3*4-1)*6
(4*3-1)*6
6*(3*4-1)
6*(4*3-1)
yes
```

## A motivating symbolic processing example

- Polynomial: built from the atom ‘x’ and numbers using ops ‘+’ and ‘\*’
- Calculate the value of a polynomial for a given substitution of x

```
% value_of(+Poly, +X, ?V): Poly has the value V, for x=X
value_of0(x, X, V) :- V = X.
value_of0(N, _, V) :-
    number(N), V = N.

value_of0(P1+P2, X, V) :-
    value_of0(P1, X, V1),
    value_of0(P2, X, V2),
    V is V1+V2.

value_of0(Poly, X, V) :-
    Poly = *(P1,P2),
    value_of0(P1, X, V1),
    value_of0(P2, X, V2),
    PolyV = *(V1,V2),
    V is PolyV.

value_of(x, X, V) :- !, V = X.
value_of(N, _, V) :-
    number(N), !, V = N.

value_of(Poly, X, V) :-
    Poly =.. [Func,P1,P2],
    value_of(P1, X, V1),
    value_of(P2, X, V2),
    PolyV =.. [Func,V1,V2],
    V is PolyV.
```

- Predicate `value_of` works for all **binary** functions supported by `is/2`.

```
| ?- value_of(exp(100,min(x,1/x)), 2, V).    ==>    V = 10.0 ? ; no
```

Building and decomposing compounds: `functor/3`

- `functor(Term, Name, Arity)`:  
 Term has the name `Name` and arity `Arity`, i.e.  
 Term has the functor `Name/Arity`.  
 (A constant `c` is considered to have the name `c` and arity 0.)
  - Call patterns:
    - `functor(+Term, ?Name, ?Arity)` – decompose `Term`
    - `functor(-Term, +Name, +Arity)` – construct a most general `Term` (\*)
  - If `Term` is output (\*), it is unified with the most general term with the given name and arity (with distinct new variables as arguments)
- Examples:
  - | `?- functor(edge(a,b,1), F, N).`      $\implies$    `F = edge, N = 3`
  - | `?- functor(E, edge, 3).`            $\implies$    `E = edge(_A,_B,_C)`
  - | `?- functor(apple, F, N).`            $\implies$    `F = apple, N = 0`
  - | `?- functor(Term, 122, 0).`          $\implies$    `Term = 122`
  - | `?- functor(Term, edge, N).`          $\implies$    **error**
  - | `?- functor(Term, 122, 1).`          $\implies$    **error**
  - | `?- functor([1,2,3], F, N).`          $\implies$    `F = '.', N = 2`
  - | `?- functor(Term, ., 2).`            $\implies$    `Term = [_A|_B]`

Building and decomposing compounds: `arg/3`

- `arg(N, Compound, A)`: the `N`th argument of `Compound` is `A`
  - Call pattern: `arg(+N, +Compound, ?A)`, where  $N \geq 0$  holds
  - Execution: The `N`th argument of `Compound` is **unified** with `A`.  
 If `Compound` has less than `N` arguments, or  $N = 0$ , `arg/3` fails
  - Arguments are **unified** – `arg/3` can also be used for instantiating a variable argument of the structure (as in the second example below).
- Examples:
  - | `?- arg(3, edge(a, b, 23), Arg).`      $\implies$    `Arg = 23`
  - | `?- T=edge(.,.,.), arg(1, T, a),`  
    `arg(2, T, b), arg(3, T, 23).`      $\implies$    `T = edge(a,b,23)`
  - | `?- arg(1, [1,2,3], A).`              $\implies$    `A = 1`
  - | `?- arg(2, [1,2,3], B).`              $\implies$    `B = [2,3]`
- Predicate `univ` can be implemented using `functor` and `arg`, and vice versa, for example:
  - `Term =.. [F,A1,A2]  $\iff$  functor(Term, F, 2), arg(1, Term, A1), arg(2, Term, A2)`
