Prolog in the family of programming languages

Programming paradigms – programming languages

Prolog

- Birth date: 1972, designed by Alain Colmerauer, Robert Kowalski
- First public implementation (Marseille Prolog):
  1973, interpreter in Fortran, A. Colmerauer, Ph. Roussel
- Second implementation (Hungarian Prolog):
  1975, interpreter in CDL, Péter Szeredi

http://dtai.cs.kuleuven.be/projects/ALP/newsletter/nov04/nav/articles/szeredi/szeredi.html

- First compiler (Edinburgh Prolog, DEC-10 Prolog):
  1977, David H. D. Warren (current syntax introduced)
- Wiki: https://en.wikipedia.org/wiki/Prolog

Prolog – PROgramming in LOGic: standard (Edinburgh) syntax

```
Standard syntax         English                         Marseille syntax
has_p(b, c).            % b has a parent c.             +has_p(b, c).
has_p(b, d).            % b has a parent d.             +has_p(b, d).
has_p(d, e).            % d has a parent e.             +has_p(d, e).
has_p(d, f).            % d has a parent f.             +has_p(d, f).

                        % for all GC, GP, P  holds
has_gp(GC, GP) :-       % GC has grandparent GP if      +has_gp(*GC, *GP)
    has_p(GC, P),       % GC has parent P and              -has_p(*GC,*P)
    has_p(P, GP).       % P has parent GP.                 -has_p(*P,*GP).
```

FOL: $\forall GC, GP. \ (\text{has\_gp}(GC, GP) \leftarrow \exists P.(\text{has\_p}(GC, P) \wedge \text{has\_p}(P, GP)))$

- Program execution is SLD resolution, which can also be viewed as pattern-based procedure invocation with backtracking
- Dual semantics: declarative and procedural
  - Slogan: WHAT <u>rather than</u> HOW
    (focus on the logic first, but then think over Prolog execution, too).

Prolog clauses and predicates - some terminology

- A Prolog program is a sequence of *clauses*
- A clause represents a statement, it can be
    - a *fact*, of the form '*head*.', e.g. `has_parent(a,b).`
    - a *rule*, of the form '*head* :- *body*.',
      e.g. `has_gp(GC, GP) :- has_p(GC, P), has_p(P, GP).`   (*)
- Read ':-' as 'if', ',' as 'and'
- A *fact* can be viewed as having an empty body, or the body `true`
- A *body* is comma-separated list of *goals*, also named *calls*
- A *head* as well as a *goal* has the form *name*(*argument*,...), or just *name*
- A functor of a *head* or a *goal* (or a term, in general) is *F/N*, where *F* is the name of the term and *N* is the number of args (also called *arity*). Example: the functor of the head of (*) is `has_gp/2`
- The functor of a clause is the functor of its head.
- The collection of clauses with the same functor is called a *predicate* or *procedure*
- Clauses of a predicate should be contiguous (you get a warning, if not)

And what happened to the *function* symbols of FOL?

- Recall: In FOL, atomic predicates have arguments that are terms, built from variables using function symbols, e.g. *lseq*(*plus*(*X*, 2), *times*(*Y*, *Z*))
- In maths this is normally written in *infix operator* notation as $X + 2 \leq Y \cdot Z$
- In Prolog, graphic characters (and sequences of such) can be used for both relation and function names: =<(+(X,2), *(Y,Z))   (1)
- As a "syntactic sweetener", Prolog supports operator notation in user interaction, i.e. (1) is normally input and displayed as X+2 =< Y*Z. However, (1) is the internal, *canonical* format
- The built-in predicate (BIP) write/1 displays its arg. using operators, while write_canonical/1 shows the canonical form

  | ?- write(1 - 2 =< 3*4). $\implies$ 1-2=<3*4
  | ?- write_canonical(1 - 2 =< 3*4). $\implies$ =<(-(1,2),*(3,4))

- Notice that the predicate arguments are not evaluated, function names act as *data constructors* (e.g. the op. - is used not only for subtraction)
- Prolog is a symbolic language, e.g. symbolic derivation is easy
- However, doing arithmetic requires special built-in predicates

Prolog built-in predicates (BIPs) for unification and arithmetic

- Unification. `X = Y`: unifies `X` and `Y`. Examples:

```
| ?- X = 1-2, Z = X*X.          ⟹    X = 1-2, Z = (1-2)*(1-2)
| ?- U = X/Y, c(X,b)=c(a,Y).     ⟹    U = a/b, X = a, Y = b
| ?- 1-2*3 = X*Y.               ⟹    no  (unification unsuccessful)
```

- Arithmetic evaluation. `X is A`: `A` is evaluated, the result is unified with `X`. `A` must be a ground arithmetic expression (ground: no free vars inside)

```
| ?- X = 2, Y is X*X+2.         ⟹    X = 2, Y = 6 ?
| ?- X = 2, 7 is X*X+2.         ⟹    no
| ?- X = 6, 7-1 is X.           ⟹    no
| ?- X is f(1,2).               ⟹    'Type Error'
```

- Arithmetic comparison. `A =:= B`: `A` and `B` are evaluated to numbers. Succeeds iff the two numbers are equal.
  (Both `A` and `B` have to be ground arithmetic expressions.)

```
| ?- X = 6, 7-1 =:= X.          ⟹    X = 6
| ?- X = 6, X*X =:= (X+3)*(X-2). ⟹    X = 6
| ?- X = 6, X+3 =:= 2*(X-2).    ⟹    no
| ?- X = 6, X+3 =:= 2*(Y-2).    ⟹    'Instantiation Error'
```

Further BIPs: `A < B, A > B, A =< B` $(\leq)$, `A >= B` $(\geq)$, `A =\= B` $(\neq)$,

An example: cryptarithmetic puzzle

- Consider this cryptarithmetic puzzle: `AD*AD = DAY`.
  Here each letter stands for a *different* digit, initial digits cannot be zeros.
  Find values for the digits `A`, `D`, `Y`, so that the equation holds.
- We'll use a library predicate `between/3` from library `between`.
  ```
  % between(+N, +M, ?X): X is an integer such that N =< X =< M,
  %                      Enumerates all such X values.
  ```
- I/O mode notation for pred. arguments (used only in comments):
  `+`: input (bound), `-`: output (unbound var.), `?`: arbitrary.
- To load a library: (in SICStus) include the line below in your program:
  ```
  :- use_module(library(between)).
  ```
  In SWI Prolog the predicate is loaded automatically.
- The Prolog predicate for solving the `AD*AD = DAY` puzzle:
  ```
  ad_day(AD, DAY) :-
      between(1, 9, A), between(1, 9, D), between(0, 9, Y),
      A =\= D, A =\= Y, D =\= Y,
      DAY is D*100+A*10+Y, AD is A*10+D,
      AD * AD =:= DAY.
  ```
- Solve this puzzle yourself: `GO+TO=OUT`

Data structures in Prolog

Prolog is a dynamically typed language, i.e. vars can take arbitrary values.
Prolog data structures correspond to FOL terms. A Prolog term can be:

- `var` (variable), e.g. `X`, `Sum`, `_a`, `_`; the last two are *void* (don't care) vars
  (If a var occurs once in a clause, prefix it with `_`, or get a WARNING!!!
  Multiple occurrences of a single `_` symbol denote different vars.)
- `constant` (0 argument function symbol):
  - `number` (`integer` or `float`), e.g. `3`, `-5`, `3.1415`
  - `atom` (symbolic constant, cf. enum type), e.g. `a`, `susan`, `=<`, `'John'`
- `compound`, also called record, structure (*n*-arg. function symbol, $n > 0$)
  A compound takes the form: *name*(arg_1, ..., arg_n), where
  - *name* is an atom, arg_i are arbitrary Prolog terms
  - e.g. `employee(name('John','Smith'),birthd(20,11,1994),'Sales')`
  - Compounds can be viewed as trees

Variables in Prolog: the logic variable

- A variable cannot be assigned (unified with) two distinct ground values:

  ```
  | ?- X = 1, X = 2.                    ⟹   no
  ```

- Two variables may be unified and then assigned a (common) value:

  ```
  | ?- X = Y, X = 2.                    ⟹   X = 2, Y = 2 ?
  ```

- The above apply to a single branch of execution. If we backtrack over a branch on which the variable was assigned, the assignment is undone, and on a new branch another assignment can be made:

  ```
  has_p(b, c).        has_p(b, d).        has_p(d, e).

  | ?- has_p(b, Y).                    ⟹   Y = c ? ; Y = d ? ; no
  ```

- A logic variable is a "first class citizen" data structure, it can appear inside compound terms:

  ```
  | ?- Emp = employee(Name,Birth,Dept), Dept = 'Sales',
          Name = name(First,Last), First = 'John'.
      ⟹   Emp = employee(name('John',Last),Birth,'Sales') ?
  ```

- The `Emp` data structure represents an arbitrary employee with given name `John` who works in the `Sales` department

The logic variable (cont'd)

- A variable may also appear several times in a compound, e.g. `name(X,X)` is a Prolog term, which will match the first argument of the employee/3 record, iff the person's first and last names are the same:

```
employee(1, employee(name('John','John'),birthd(2000,12,21),'Sales')).
employee(2, employee(name('Ann','Kovach'),birthd(1988,8,18 ),'HR')).
employee(3, employee(name('Peter','Peter'),birthd(1970,2,12 ),'HR')).

| ?- employee(Num, Emp), Emp = employee(name(_X,_X),_,_).
Num = 1, Emp = employee(name('John','John'),birthd(2000,12,21),'Sales') ? ;
Num = 3, Emp = employee(name('Peter','Peter'),birthd(1970,2,12),'HR') ? ; no
```
- If a variable name starts with an underline, e.g. `_X`, its value is not displayed by the interactive Prolog shell (often called the *top level*)

Classification of Prolog terms

- The taxonomy of Prolog terms – corresponding built-in predicates (BIPs)

`var(X)`	X is a variable
`nonvar(X)`	X is not a variable
`atomic(X)`	X is a constant (atom or number)
`compound(X)`	X is a compound
`number(X)`	X is a number
`atom(X)`	X is an atom
`float(X)`	X is a floating point number
`integer(X)`	X is an integer

```
                    Term
            _____|_____
           |                 |
          var              nonvar
                        _____|_____
                       |           |
                    atomic     compound
                   ___|___
                  |       |
               number    atom
               __|__
              |     |
            float integer
```
- The five coloured BIPs correspond to the five basic term types.
- Two further type-checking BIPs:
  - `simple(X)`: X is not compound, i.e. it is a variable or a constant.
  - `ground(X)`: X is a constant or a compound with no (uninstantiated) variables in it.

Another syntactic "sweetener" – list notation

- A Prolog list $[a,b,\ldots]$ represents a sequence of terms (cf. linked list)

```
| ?- L = [a,b,c], write_canonical(L).
'.'(a,'.'(b,'.'(c,[])))
```

(Since version 7, SWI Prolog uses '[|]', instead of '.' :-((((.)

- The *head* of a list is its first element, e.g. L's head: a
  the *tail* is the list of all but the first element, e.g. L's tail: $[b,c]$
- One often needs to split a list to its head and tail: List = .(Head, Tail).
  The "square bracketed" counterpart: List = [Head|Tail]
- Further sweeteners: $[E_1,E_2,\ldots,E_n|Tail] \equiv [E_1|[E_2|\ldots,[E_n|Tail]\ldots]]$
  $$[E_1,E_2,\ldots,E_n] \equiv [E_1,E_2,\ldots,E_n|[]]$$

Open ended and proper lists

- Example:
  ```
  % head0(L): L's first element is 0.
  head0(L) :- L = [0|_].  % '_' is a void, don't care variable
  % singleton(L): L has a single element.
  singleton([_]).
  | ?- singleton(L1).  ⇒      L1 = [_A]      % L1 = [_A|[]] is a *proper* list
  | ?- head0(L2).      ⇒      L2 = [0|_A]    % L2 is an *open ended* list
  ```
- A Prolog term is called an *open ended* (or *partial*) list iff
  - either it is an unbound variable,
  - or it is a nonempty list structure (i.e. of the form [_|_])
    and its tail is *open ended*,

  i.e. if sooner or later an unbound variable appears as the tail.
- A list is *closed* or *proper* iff sooner or later an [] appears as the tail
- Further examples: [X,1,Y] is a proper list, [X,1|Z] is open ended.

Working with lists – some practice

(Each occurrence of a void variable (`_`) denotes a different variable.)

```
| ?- [1,2] = [X|Y].              ⟹    X = 1, Y = [2] ?
| ?- [1,2] = [X,Y].              ⟹    X = 1, Y = 2 ?
| ?- [1,2,3] = [X|Y].            ⟹    X = 1, Y = [2,3] ?
| ?- [1,2,3] = [X,Y].            ⟹    no
| ?- [1,2,3,4] = [X,Y|Z].        ⟹    X = 1, Y = 2, Z = [3,4] ?
| ?- L = [a,b], L = [_,X|_].     ⟹    ..., X = b ?  % X = 2nd elem
| ?- L = [a,b], L = [_,X,_|_].   ⟹    no ?  % length >= 3, X = 2nd elem
| ?- L = [1|_], L = [_,2|_].     ⟹    L = [1,2|_A] ? % open ended list
```

Programming with lists – simple example

- Recall: I/O mode notation for pred. arguments (only in comments):
  +: input (bound), –: output (unbound var.), ?: arbitrary.
- Write a predicate that checks if all elements in a list are the same. Let's call such a list A-boring, where A is the element appearing repeatedly.
- Remember, you can read ':-' as 'if', ',' as 'and'

```
% boring(+L, ?A): List L is A-boring.
boring([], _)    % [] is A-boring for every A.
boring(L, A) :-  % List L is A-boring, if
  L=[A|L1],      %   L's head equals A and
  boring(L1, A). %   L's tail is A-boring.
```

Programming with lists – further examples

- Given a list of numbers, calculate the sum of the list elements.
- Remember, you can do arithmetic calculations with '`is`'

```
% sum(+L, ?Sum): L sums to Sum. (L is a list of numbers.)
sum([], 0).         % [] sums to 0.
sum([H|T], Sum) :-  % A list with head H and tail T sums to Sum if
  sum(T, Sum0),     %   T sums to Sum0 and
  Sum is Sum0+H.    %   Sum is the value of Sum0+H.
```

- Given two arbitrary lists, check that they are of equal length.

```
% same_length(?L1, ?L2): Lists L1 and L2 are of equal length.
same_length([], []).    % [] has the same length as []
same_length(L1, L2) :-  % L1 and L2 are of equal length if
  L1 = [_|T1],          % the tail of L1 is T1 and
  L2 = [_|T2],          % the tail of L2 is T2 and
  same_length(T1, T2).  % the T1 and the T2 are of equal length.
```

Another recursive data structure – binary tree

- A binary tree data structure can be defined as being
  - either a leaf (`leaf`) which contains an integer (`value`)
  - or a node (`node`) which contains two subtrees (`left`,`right`)
- Defining binary tree structures in C and Prolog:

```
% Declaration of a C structure
enum treetype Leaf, Node;
struct tree {
  enum treetype type;
  union {
    struct { int value;
            } leaf;

    struct { struct tree *left;
             struct tree *right;
            } node;
  } u;
};
```

```
% No need to define types in Prolog
% A type-checking predicate can be
% written, if this check is needed:

% is_tree(T): T is a binary tree
is_tree(leaf(Value)) :-
    integer(Value).
is_tree(node(Left,Right)) :-
    is_tree(Left),
    is_tree(Right).
```

Recall: `integer(Value)` is a BIP which
succeeds if and only if `v` is an integer.

Calculating the sum of numbers in the leaves of a binary tree

- Calculating the sum of the leaves of a binary tree:
    - if the tree is a leaf, return the integer in the leaf
    - if the tree is a node, add the sums of the two subtrees

```
% C function (declarative)
int tree_sum(struct tree *tree) {
  switch(tree->type) {
  case Leaf:
   return tree->u.leaf.value;
  case Node:
   return
    tree_sum(tree->u.node.left) +
    tree_sum(tree->u.node.right);
    }
}
```

```
% Prolog procedure
% tree_sum(+T, ?S):
% The sum of the leaves
% of tree T is S.
tree_sum(leaf(Value), S) :-
        S = Value.
tree_sum(node(Left,Right), S) :-

        tree_sum(Left, S1),
        tree_sum(Right, S2),
        S is S1+S2.
```

Sum of Binary Trees – a sample run

```
% sicstus
SICStus 4.3.5 (...)
| ?- consult(tree).    % alternatively: compile(tree). or [tree].
% consulting /home/szeredi/examples/tree.pl...
% consulted /home/szeredi/examples/tree.pl in module user, (...)
| ?- tree_sum(node(leaf(5),
                   node(leaf(3), leaf(2))), Sum).
Sum = 10 ? ; no
| ?- tree_sum(leaf(10), 10).
yes
| ?- tree_sum(leaf(10), Sum).
Sum = 10 ? ; no
| ?- tree_sum(Tree, 10).
Tree = leaf(10) ? ;
! Instantiation error in argument 2 of is/2
! goal:  10 is _73+_74
| ?- halt.
```

The cause of the error: the built-in arithmetic is one-way: the goal `10 is S1+S2` causes an error!

Contents

3 Declarative Programming with Prolog

Two Prolog execution models

- The Goal Reduction model
  - a reformulation of the resolution proof technique
  - good for visualizing the search tree
- The Procedure Box model
  - reflects actual implementation better
  - used by the Prolog trace mechanism

Goal reduction vs. resolution – a propositional example

```
get_fined :-    driving_fast, raining.        (1)
driving_fast :- in_a_hurry.                    (2)
...
in_a_hurry.                                    (3)
raining.                                       (4)
```

- To show that the goal `get_fined` holds, goal reduction repeatedly *reduces* it to other goals using clauses (1)-(4)
- When an empty goal (true) is obtained the goal gets proved.

```
(g1)   get_fined              % (g1) is reduced, using (1), to    (g2)
(g2)   driving_fast, raining  % (g2) is reduced, using (2), to    (g3)
(g3)   in_a_hurry,   raining  % (g3) is reduced, using (3), to    (g4)
(g4)   raining               % (g4) is reduced, using (4), to    (g5)
(g5)   ∎ (empty goal) ≡ true
```

Goal reduction vs. resolution (cnt'd)

```
+get_fined       -driving_fast -raining.        (1)
+driving_fast    -in_a_hurry                     (2)
...
+in_a_hurry.                                     (3)
+raining.                                        (4)
```

- To show that `get_fined` holds, resolution does an indirect proof
- Assume `get_fined` does not hold, deduce false (contradiction) using clauses (1)–(4)

```
(g1)  -get_fined              % (g1) and          (1) implies (g2)
(g2)  -driving_fast -raining  % (g2) and          (2) implies (g3)
(g3)  -in_a_hurry   -raining  % (g3) and          (3) implies (g4)
(g4)  -raining               % (g4) and          (4) implies (g5)
(g5)   □ (empty clause) ≡ false
```

The Goal Reduction model – the grandparent example

- Goal reduction takes a goal, i.e. a *conjunction* of subgoals G and using a clause C reduces it to goal G',

  so that $G' \rightarrow G$

- E.g. reducing G = has_gp(b, X) using (gp1) gives
  G' = has_p(b, P1), has_p(P1, X)

```
has_p(b, c).            % (p1)
has_p(b, d).            % (p2)
has_p(d, e).            % (p3)
has_p(d, f).            % (p4)

has_gp(GC, GP) :-
        has_p(GC, P),
        has_p(P, GP).   % (gp1)
```

```
| ?- has_gp(b, X).
```

has_gp(b, X)

(gp1)

has_p(b, P1), has_p(P1, X)

(p1)   (p2)
P1=c   **P1=d**

has_p(c, X)

has_p(d, X)

(blind alley –– backtrack)

(p3)   (p4)
X=e   **X=f**

■   ■

(empty conjunction = true)   (empty conjunction)
(success)   (success)

Resolution – same example

- Resolution takes a negated goal *NG* (which is a *disjunction* of neg. literals) and using a clause *C* deduces new negated goal *NG'*,

  so that $NG \rightarrow NG'$

- E.g. resolving NG = `-has_gp(b, X)` using (gp1) gives

  NG' = `-has_p(b, P1) -has_p(P1, X)`

```
+has_p(b, c).              % (p1)
+has_p(b, d).              % (p2)
+has_p(d, e).              % (p3)
+has_p(d, f).              % (p4)

+has_gp(GC, GP)
        -has_p(GC, P),
        -has_p(P, GP).     % (gp1)

-has_gp(b, X).
```

-has_gp(b, X)

(gp1)

-has_p(b, P1) -has_p(P1, X)

The Goal Reduction model (ADVANCED)

Goal reduction: a goal is viewed as a conjunction of subgoals

- Given a goal $G = A, B, \ldots$ and a clause $(A \text{ :- } D, \ldots)$
  $G' = B, \ldots, D, \ldots$ is obtained as the new goal

Goal reduction is the same as resolution, but viewed as backwards reasoning

- Resolution:
  - to prove $A \wedge B \wedge \ldots$, we negate it obtaining $\neg G_0 = \text{-A -B} \ldots$
  - resolution step : clause $Cl = (\text{+A -D} \ldots)$ resolved with $\neg G_0$
    produces $\neg G_1 = \text{-D} \ldots \text{-B} \ldots$
    $$\neg G_n \wedge Cl \rightarrow \neg G_{n+1} \qquad \text{(resolution)}$$
  - success of indirect proof: reaching an empty clause $\square \equiv \text{false}$
- Goal reduction:
  - to prove $A \wedge B \wedge \ldots$, we start with $G_0 = \text{A, B, } \ldots$
  - reduction step : using $Cl = (\text{A :- D, } \ldots)$ one can reduce G_0 to
    $G_1 = \text{D, } \ldots, \text{B, } \ldots$
    $$G_{n+1} \wedge Cl \rightarrow G_n \qquad \text{(reduction)}$$
  - success of the reduction proof: reaching an empty goal $\blacksquare \equiv \text{true}$
- the (resolution) and (reduction) reasoning rules are equivalent!

The definition of a goal reduction step

Reduce a goal G to a new goal G' using a program clause Cl_i:

- Split goal G into the first subgoal G_F and the residual goal G_R
- **Copy** clause Cl_i, i.e. rename all variables to new ones, and split the copy to a head H and body B
- **Unify** the goal G_F and the head H
  - If the unification fails, exit the reduction step with failure
  - If the unification succeeds with a substitution σ, return the new goal $G' = (B, G_R)\sigma$ (i.e. apply σ to both the body and the residual goal)

E.g., slide 111: $G = $ `has_gp(b, X)` using (gp1) $\Rightarrow G' = $ `has_p(b, P1),has_p(P1, X)`

Reduce a goal G to a new goal G' by executing a built-in predicate (BIP)

- Split goal G into the first, BIP subgoal G_F and the residual goal G_R
- **Execute** the BIP G_F
  - If the BIP fails then exit the reduction step with failure
  - If the BIP succeeds with a substitution σ then return the new goal $G' = G_R\sigma$

The goal reduction model of Prolog execution – outline

- This model describes how Prolog builds and traverses a search tree
- A web app for practicing the model: `https://ait.plwin.dev/P1-1`
- The inputs:
    - a Prolog program (a sequence of clauses), e.g. the `has_gp` program
    - a goal, e.g. `:- has_gp(b, GP).`
      extended with a special goal, carrying the solution: `answer(Sol)`:
      ```
      :- has_gp(b, GP),answer(GP).     % Who are the grandparents of a?
      :- has_gp(Ch,GP),answer(Ch-GP).  % Which are the child-gparent pairs?
      ```
- When only an `answer` goal remains, a solution is obtained
- Possible outcomes of executing a Prolog goal:
    - Exception (error), e.g. `:- Y = apple, X is Y+1.`

      (This is not discussed further here)
    - Failure (no solutions), e.g. `:- has_p(c, P), answer(P).`
   - Success (1 or more solutions), e.g. `:- has_p(d, P), answer(P).`

The main data structures used in the model

- There are only two (imperative, mutable) variables in this model:
  `Goal`: the current goal sequence, `ChPSt` the stack of choice points (ChPs)
- If, in a reduction step, two or more clause heads unify (match) the first
  subgoal, a new `ChPSt` entry is made, storing:
  - the list of clauses with possibly matching heads
  - the current goal sequence (i.e. `Goal`)

ChPoint name	Clause list	Goal	
CHP2	[p3,p4]	(4)	`hasP(d,Y),answer(b-Y).`
CHP1	[p2,p3,p4]	(2)	`hasP(X,P),hasP(P,Y),answer(X-Y).`

- At a failure, the top entry of the `ChPSt` is examined:
  - the goal stored there becomes the current `Goal`,
  - the first element of the list of clauses is removed, the second is
    remembered the as the "current clause",
  - if the list of clauses is now a singleton, the top entry is removed,
  - finally the `Goal` is reduced, using the current clause.
- If, at a failure, `ChPSt` is empty, execution ends.

The flowchart of the Prolog goal reduction model

(Double arrows indicate a jump to the step in the pink circle, i.e. execution continues at the given red circle.)

Remarks on the flowchart

- There are seven different execution steps: **S1**–**S7**, where **S1** is the initial (but also an intermediate) step, and **S7** represents the final state.
- The main task of **S1** is to branch to one of **S2**–**S6**:
    - when Goal contains an answer goal only ⇒ **S6**;
    - when the first subgoal of Goal calls a BIP ⇒ **S5**;
    - otherwise the first subgoal calls a user predicate. Here a set of clauses is selected which *contains* all clauses whose heads match the first subgoal (this may be a *superset* of the matching ones). Based on the number of clauses ⇒ **S2**, **S3** or **S4**.
- **S2** creates a new ChPSt entry, and ⇒ **S3** (to reduce with the first clause).
- **S3** performs the reduction. If that fails ⇒ **S4**, otherwise ⇒ **S1**.
- **S4** retrieves the next clause from the top ChPSt entry, if any (⇒ **S3**), otherwise execution ends (⇒ **S7**).
- In **S5**, similarly to **S3**, if the BIP succeeds ⇒ **S1**, otherwise ⇒ **S4**.
- In **S6**, the solution is displayed and further solutions are sought (⇒ **S4**).

The Procedure Box execution model – example

- The procedure box execution model of `has_gp`

```
has_gp(GC, GP) :- has_p(GC, P), has_p(P, GP).
```

```
has_p(b, c).
has_p(b, d).
has_p(d, e).
has_p(d, f).
```

Prolog tracing, based on the four port box model

```
| ?- consult(gp3).
% consulting gp3.pl...
% consulted gp3.pl ...
yes
| ?- listing.
has_gp(Ch, G) :-
        has_p(Ch, P),
        has_p(P, G).

has_p(b, c).
has_p(b, d).
has_p(d, e).
has_p(d, f).

yes
| ?- trace.
% The debugger will ...
yes
```
```
| ?- has_gp(Ch, f).
```

Det?	BoxId	Depth	Port	Goal
	1	1	Call:	has_gp(Ch,f) ?
	2	2	Call:	has_p(Ch,P) ?
?	2	2	Exit:	has_p(b,c) ?
	3	2	Call:	has_p(c,f) ?
	3	2	Fail:	has_p(c,f) ?
	2	2	Redo:	has_p(b,c) ?
?	2	2	Exit:	has_p(b,d) ?
	4	2	Call:	has_p(d,f) ?
	4	2	Exit:	has_p(d,f) ?
				No choice left in box 4, box removed (no ?)
?	1	1	Exit:	has_gp(b,f) ?

```
Ch = b ? ;
```

Det?	BoxId	Depth	Port	Goal
	1	1	Redo:	has_gp(b,f) ?
	2	2	Redo:	has_p(b,d) ?
?	2	2	Exit:	has_p(d,e) ?
	5	2	Call:	has_p(e,f) ?
	5	2	Fail:	has_p(e,f) ?
	2	2	Redo:	has_p(d,e) ?
	2	2	Exit:	has_p(d,f) ?
				No choice left in box 2, box removed (no ?)
	6	2	Call:	has_p(f,f) ?
	6	2	Fail:	has_p(f,f) ?
	1	1	Fail:	has_gp(Ch,f) ?

```
no
| ?-
```

The procedure-box of multi-clause predicates

'Sister in law' can be one's spouse's sister; or one's brother's wife:

```
has_sister_in_law(X, Y) :-
    has_spouse(X, S), has_sister(S, Y).
has_sister_in_law(X, Y) :-
    has_brother(X, B), has_wife(B, Y).
```

The procedure-box of a "database" predicate of facts

- In general in a multi-clause predicate the clauses have different heads
- A database of facts is a typical example:

  ```
  has_p(b, c).
  has_p(b, d).
  ```

- These clauses can be massaged to have the same head:

  ```
  has_p(Ch, P) :-  Ch = b, P = c.
  has_p(Ch, P) :-  Ch = b, P = d.
  ```

- Consequently, the procedure-box of this predicate is this:

Contents

3. Declarative Programming with Prolog

Summary – syntax of Prolog predicates, clauses

Example

```
% A  predicate with two clauses, the functor is: tree_sum/2
tree_sum(leaf(Val), Val).       %                     clause 1, fact
tree_sum(node(Left,Right), S) :- %        head      \
    tree_sum(Left, S1),         % goal     \       |
    tree_sum(Right, S2),        % goal      | body | clause 2, rule
    S is S1+S2.                 % goal     /       /
```

Syntax

$\langle$ program $\rangle$	::=	$\langle$ predicate $\rangle$ ...	{i.e. a sequence of predicates}
$\langle$ predicate $\rangle$	::=	$\langle$ clause $\rangle$ ...	{with the same functor}
$\langle$ clause $\rangle$	::=	$\langle$ fact $\rangle$.␣ |	
		$\langle$ rule $\rangle$.␣	
$\langle$ fact $\rangle$	::=	$\langle$ head $\rangle$	
$\langle$ rule $\rangle$	::=	$\langle$ head $\rangle$:-$\langle$ body $\rangle$	{clause functor = head functor}
$\langle$ body $\rangle$	::=	$\langle$ goal $\rangle$, ...	{i.e. a seq. of goals sep. by commas}
$\langle$ head $\rangle$	::=	$\langle$ callable term $\rangle$	{atom or compound}
$\langle$ goal $\rangle$	::=	$\langle$ callable term $\rangle$	{or a variable, if instantiated to a callable}

Prolog terms (canonical form)

Example – a clause head as a term

```
% tree_sum(node(Left,Right), S)    % compound term, has the
% _____ _____  _      % functor tree_sum/2
%     |          |          |
% compound name  \          argument, variable
%                 \ - argument, compound term
```

Syntax

⟨ term ⟩	::=	⟨ variable ⟩ |	{has no functor}
		⟨ constant ⟩ |	{⟨ constant ⟩/0}
		⟨ compound term ⟩ |	{⟨ comp. name ⟩/⟨ # of args ⟩}
		. . . extensions . . .	{lists, operators}
⟨ constant ⟩	::=	⟨ atom ⟩ |	{symbolic constant}
		⟨ number ⟩	
⟨ number ⟩	::=	⟨ integer ⟩ | ⟨ float ⟩	
⟨ compound term ⟩	::=	⟨ comp. name ⟩ (⟨ argument ⟩, . . .)	
⟨ comp. name ⟩	::=	⟨ atom ⟩	
⟨ argument ⟩	::=	⟨ term ⟩	
⟨ callable term ⟩	::=	⟨ atom ⟩ | ⟨ compound term ⟩	

Lexical elements

Examples

```
% variable:        Fact FACT _fact X2 _2 _
% atom:            fact ≡ 'fact' 'István' [] ; ',' += ** \= ≡ '\\='
% number:          0 -123 10.0 -12.1e8
% not an atom:     !=, István
% not a number:    1e8 1.e2
```

Syntax

⟨ variable ⟩	::=	⟨ capital letter ⟩⟨ alphanum ⟩... |
		_ ⟨ alphanum ⟩...
⟨ atom ⟩	::=	'⟨ quoted char ⟩... ' |
		⟨ lower case letter ⟩⟨ alphanum ⟩... |
		⟨ sticky char ⟩... | ! | ; | [] | {}
⟨ integer ⟩	::=	{signed or unsigned sequence of digits }
⟨ float ⟩	::=	{ a sequence of digits with a compulsory decimal point in between, with an optional exponent}
⟨ quoted char ⟩	::=	{any non ' and non \ character} | \ ⟨ escaped char ⟩
⟨ alphanum ⟩	::=	⟨ lower case letter ⟩ | ⟨ upper case letter ⟩ | ⟨ digit ⟩ | _
⟨ sticky char ⟩	::=	+ | − | * | / | \ | $ | ^ | < | > | = | ' | ~ | : | . | ? | @ | # | &

Comments and layout in Prolog

- Comments
    - From a % character till the end of line
    - From /* till the next */
- Layout (spaces, newlines, tabs, comments) can be used freely, except:
    - No layout allowed between the name of a compound and the "("
    - If a prefix operator (see later) is followed by "(", these have to be separated by layout
    - Clause terminator (.␣): a stand-alone full stop (i.e., one not preceded by a sticky char), followed by layout
- The recommended formatting of Prolog programs:
    - Write clauses of a predicate continuously, no empty lines between
    - Precede each pred. by an empty line and a spec (head comment)
      ```
      % predicate_name(A1, ..., An): A declarative sentence (statement)
      % describing the relationship between terms A1, ..., An
      ```
    - Write the head of the clause at the beginning of a line, and prefix each goal in the body with an indentation of a few (8 recommended) spaces.

   - Executable specifications
   - Block declarations
   - Further reading

Disjunctions

- Disjunctions (i.e. subgoals separated by "or") can appear as goals
- A disjunction is denoted by semicolon (";")
- Enclose the whole disjunction in parentheses, align chars (`,`, `;` and `)`

```
has_sister_in_law(X, Y) :-
    (   has_spouse(X, S), has_sister(S, Y)
    ;   has_brother(X, B), has_wife(B, Y)
    ).
```

- The above predicate is equivalent to:

```
has_sister_in_law(X, Y) :- has_spouse(X, S), has_sister(S, Y).
has_sister_in_law(X, Y) :- has_brother(X, B), has_wife(B, Y).
```

- A disjunction is itself a valid goal, it can appear in a conjunction:

```
has_ancestor(X, A) :-
    has_parent(X, P), (   A = P
                      ;   has_ancestor(P, A)
                      ).
```

Can you make an equivalent variant which does not use ";"?

Disjunctions, continued

- An example with multiple disjunctions:

```
% first_1(L): the first nonzero element of L is 1.
first_1([A,B,C]) :-
        (    A = 1
        ;    A = 0,
             (    B = 1
             ;    B = 0, C = 1
             )
        ).
```

- Note: the `V=Term` goals can no longer be got rid of in disjunctions
- Comma binds more tightly than semicolon, e.g.

  `p :- ( q, r ; s ) ≡ p :- ((q, r) ; s).`

  Please, never enclose disjuncts (goals on the sides of `;`) in parentheses!
- You can have more than two-way "or"s:

  `p :- ( a ; b ; c ; ...)` which is the same as

  `p :- ( a ; (b ; (c ; ...)))`
- Please, do not use the unnecessary parentheses (colored red)!

Expanding disjunctions to helper predicates

- Example: `p :- q, (r ; s).`

  Distributive expansion inefficient, as it calls `q` twice:

  ```
  p :- q, r.
  p :- q, s.
  ```

- For an efficient solution introduce a helper predicate. Example:

  ```
  t(X, Z) :-
       p(X,Y),
       (   q(Y,U), r(U,Z)
       ;   s(Y, Z)
       ;   t(Y), w(Z)
       ),
       v(X, Z).
  ```

- Collect variables that occur both inside and outside the disj. – Y, Z.

- Define a helper predicate – `aux(Y,Z)` – with these vars as args, transform each disjunct to a separate clause of the helper predicate:

  ```
  aux(Y, Z) :- q(Y,U), r(U,Z).
  aux(Y, Z) :- s(Y, Z).
  aux(Y, Z) :- t(Y), w(Z).
  ```

- Replace the disjunction with a call of the helper predicate:

  ```
  t(X, Z) :- p(X, Y), aux(Y, Z), v(X, Z).
  ```

The if-then-else construct

- When the two branches of a disjunction exclude each other, use the if-then-else construct (condition -> then ; else). Example:

```
% pow(A, E, P): P is A to the power E.
pow(A, E, P) :-                    pow1(A, E, P) :-
    (   E > 0, E1 is E-1,   ⟹        (   E > 0 -> E1 is E-1,
        pow(A, E1, P1),                  pow(A, E1, P1),
        P is A*P1                        P is A*P1
    ;   E = 0, P = 1                 ;   E = 0, P = 1
    ).                               ).
```

- pow1 is about 25% faster than pow and requires much less memory
- The atom -> is a standard operator
- The construct (Cond -> Then ; Else) is executed by first executing Cond. If this succeeds, Then is executed, otherwise Else is executed.
- **Important**: Only the first solution of Cond is used for executing Then. The remaining solutions are discarded!
- Note that (Cond -> Then ; Else) looks like a disjunction, but it is not
- The else-branch can be omitted, it defaults to false.

Defining "childless" using if-then-else

- Given the `has_parent/2` predicate, define the notion of a `childless` person
- If we can find a child of a GIVEN person, then `childless` should fail, otherwise it should succeed.

```
% childless(+Person): A given Person has no children
childless(Person) :-      (   has_parent(_, Person) -> fail
                          ;   true
                          ).
```

- What happens if you call `childless(P)`, where `P` is an unbound var? Will it enumerate childless people in `P`? No, it will simply fail.
- The above if-then-else can be simplified to:

```
childless(Person) :- \+ has_parent(_, Person).
```

- "`\+`" is called Negation by Failure, "`\+ G`" runs by executing `G`:
  - if `G` fails "`\+ G`" succeeds.
  - if `G` succeeds "`\+ G`" fails (ignoring further solutions of `G`, if any)
- Since a failed goal produces no bindings, "`\+ G`" will never bind a variable.
- Read "`\+`" as "not provable", cf. $\nvdash$ tilted slightly to the left.

Open and closed world assumption

has_parent(a, b). has_parent(a, c). has_parent(c, d).   (1)-(3)

- Does (1)-(3) imply that a is childless: $\varphi = \forall x.\neg \text{has\_parent}(x, a)$?
- No. Although has_parent(Ch, a) cannot be proven, φ does not hold!
- But in the world of databases we do conclude that a is childless. . .
- Databases use the Closed World Assumption (CWA): anything that cannot be proven is considered false.
- Mathematical logic uses the Open World Assumption (OWA)
  - A statement S follows from a set of statements P (premises), if S holds in any world (interpretation) that satisfies P.
  - thus φ is not a logical consequence of (1)-(3)
- Classical logic (OWA) is monotonic:
  the more you know, the more you can deduce
- Negation by failure (CWA) is non-monotonic:
  add the fact "has_parent(e, a)." to (1)-(3) and \+ has_parent(_, a) will fail.

Checking inequality – siblings and cousins

```
has_p('Charles', 'Elizabeth').  has_p('Andrew',   'Elizabeth').
has_p('William', 'Charles').     has_p('Beatrice', 'Andrew').
has_p('Harry',   'Charles').     has_p('Eugenie',  'Andrew').
```

- Recall homework L4, define predicate `has_sibling/2`, first attempt:

  `has_sibling0(A, B) :- \+ A = B, has_p(A, P), has_p(B, P).`

- `has_sibling0` does not work properly, e.g. this goal fails:

  `| ?- has_sibling0('Charles', X).`

  because `\+ 'Charles' = X` fails (as `'Charles' = X` succeeds)

- Negated goals should be instantiated as much as possible,
  therefore always place them at the end of the body:

  `has_sibling(A, B) :- has_p(A, P), has_p(B, P), \+ A = B.`

- Define `has_cousin/2` (using `has_gp/2`, the "has grandparent" predicate)

  ```
  has_cousin(A, B) :-
          has_gp(A, GP), has_gp(B, GP), \+ has_sibling(A, B), A \= B.
  ```

- Note that the BIP `A \= B` is equivalent to `\+ A = B`

The relationship of if-then-else and negation

- Negation can be fully defined using if-then-else

```
                                        (    p -> false
    \+ p                    ≡           ;    true
                                        )
```

- If-then-else can be transformed to a disjunction with a negation:

```
(    cond -> then                       (    cond, then
;    else               ⟹              ;    \+ cond, else
)                                       )
```

  These are equivalent only if `cond` succeeds at most once.
  The if-then-else is more efficient (no choice point left).

- As semicolon is associative, there is no need to use nested parentheses
  (...) if multiple if-then-else branches are present (and please don't):

```
(   cond1 -> then1                      (   cond1 -> then1
;   (    cond2 -> then2                  ;   cond2 -> then2
;   (  (...)  )          ⟹              ;   (...)
    )                                    ;   else
;   else                                 )
)
```

The procedure-box of disjunctions

A disjunction can be transformed into a multi-clause predicate
```
has_sister_in_law(X, Y) :-
    (   has_spouse(X, S), has_sister(S, Y)
    ;
        has_brother(X, B), has_wife(B, Y)
    ).
```

```
has_sister_in_law(X, Y) :-
    has_spouse(X, S), has_sister(S, Y).
has_sister_in_law(X, Y) :-
    has_brother(X, B), has_wife(B, Y).
```

The procedure box for if-then-else

```
% ha(+N, ?D, ?A): D has A as their Nth generation ancestor (N>0 int)
% The 1st,      2nd,          3rd generation ancestors are
%      parents, grandparents, great-grandparents etc.
ha(N, D, A) :-
        (   N = 1 -> hp(D, A)                        % hp(D, A): D has a parent A
        ;   N > 1, M is N-1, hp(D, P), ha(M, P, A)
        ).
```

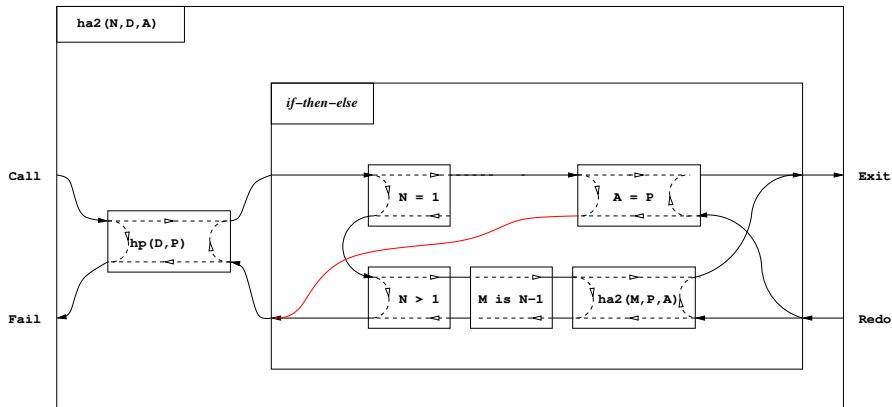

- Failure of the "then" part leads to failure of the whole if-then-else construct

The if-then-else box, continued

- When an if-then-else occurs in a conjunction, or there are multiple clauses, then it requires a separate box

```
ha2(N, D, A) :- hp(D, P), (   N = 1 -> A = P
                          ;   N > 1, M is N-1, ha2(M, P, A)
                          ).
```

Introducing operators

- Example: `S is -S1+S2` is equivalent to: `is(S, +(-(S1),S2))`
- Syntax of terms using operators
  - ⟨ comp. term ⟩ ::=
    -     ⟨ comp. name ⟩ (⟨ argument ⟩, . . .)   {so far we had this}
    - | ⟨ argument ⟩ ⟨ operator name ⟩ ⟨ argument ⟩   {infix term}
    - | ⟨ operator name ⟩ ⟨ argument ⟩   {prefix term}
    - | ⟨ argument ⟩ ⟨ operator name ⟩   {postfix term}
    - | (⟨ term ⟩)   {parenthesized term}

  - ⟨ operator name ⟩ ::= ⟨ comp. name ⟩   {if declared as an operator}
- The built-in predicate for defining operators:
  - `op(Priority, Type, Op)` or   `op(Priority, Type, [Op`$_1$`,Op`$_2$`,...])`:
    - `Priority`: an int. between 1 and 1200 – smaller priorities bind tighter
    - `Type` determines the placement of the operator and the associativity:
      - infix: `yfx, xfy, xfx`; prefix: `fy, fx`; postfix: `yf, xf` (`f` – op, `x, y` – args)
    - `Op` or `Op`$_i$: an arbitrary atom
- The call of the BIP `op/3` is normally placed in a directive, executed immediately when the program file is loaded, e.g.:
  - `:- op(800, xfx, [has_tree_sum]).`   `leaf(V) has_tree_sum V.`

Characteristics of operators

Operator properties implied by the operator type

Type			Class	Interpretation
left-assoc.	right-assoc.	non-assoc.		
`yfx`	`xfy`	`xfx`	infix	X `f` $Y \equiv$ `f(X, Y)`
	`fy`	`fx`	prefix	`f` $X \equiv$ `f(X)`
`yf`		`xf`	postfix	X `f` $\equiv$ `f(X)`

Parentheses implied by operator priorities and associativities

- `a/b+c*d` $\equiv$ `(a/b)+(c*d)` as the priority of `/` and `*` (400) is less than the priority of `+` (500)   smaller priority = **stronger** binding

- `a-b-c` $\equiv$ `(a-b)-c` as operator – has type `yfx`, thus it is left-associative, i.e. it binds to the left, the leftmost operator is parenthesized first
                   (the position of `y` wrt. `f` shows the direction of associativity)

- `a^b^c` $\equiv$ `a^(b^c)` as `^` has type `xfy`, therefore it is right-associative

- `a=b=c` $\Longrightarrow$ syntax error, as `=` has type `xfx`, it is non-associative

- the above also applies to different operators of same type and priority:
  `a+b-c+d` $\equiv$ `((a+b)-c)+d`

Standard built-in operators

Standard operators

```
1200   xfx   :- -->
1200    fx   :- ?-
1100   xfy   ;
1050   xfy   ->
1000   xfy   ','
 900    fy   \+
 700   xfx   = \= =..
              < =< =:= =\=
              > >= is
              == \==
              @< @=< @> @>=
 500   yfx   + - /\ \/
 400   yfx   * / // rem
              mod << >>
 200   xfx   **
 200   xfy   ^
 200    fy   - \
```

**Further built-in operators
of SICStus Prolog**

```
1150    fx   mode public dynamic
              volatile discontiguous
              initialization multifile
              meta_predicate block
1100   xfy   do
 900    fy   spy nospy
 550   xfy   :
 500   yfx   \
 200    fy   +
```

Operators – additional comments

- The "comma" is heavily overloaded:
  - it separates the arguments of a compound term
  - it separates list elements
  - it is an `xfy` op. of priority 1000, e.g.:
    `(p:-a,b,c)≡:-(p,','(a,','(b,c)))`

- Ambiguities arise, e.g. is `p(a,b,c)` $\overset{?}{\equiv}$ `p((a,b,c))`?

- Disambiguation: if the outermost operator of a compound argument has priority $\geq$ 1000, then it should be enclosed in parentheses

```
| ?- write_canonical((a,b,c)).  ⇒  ','(a,','(b,c))

| ?- write_canonical(a,b,c).    ⇒  Error: ! write_canonical/3 does not exist

| ?- write_canonical((hgp(A,B):-hp(A,C),hp(C,B))).

                                ⇒  :-(hgp(A,B),','(hp(A,C),hp(C,B)))
```

- Note: an unquoted comma (,) is an operator, but not a valid atom

Functions and operators allowed in arithmetic expressions

- The Prolog standard prescribes that the following functions can be used in arithmetic expressions:

plain arithmetic:

```
+X, -X, X+Y, X-Y, X*Y, X/Y,
X//Y (int. division, truncates towards 0),
X div Y (int. division, truncates towards −∞),
X rem Y (remainder wrt. //),
X mod Y (remainder wrt. div),
X**Y, X^Y (both denote exponentiation)
```

conversions:

```
float_integer_part(X), float_fractional_part(X), float(X),
round(X), truncate(X), floor(X), ceiling(X)
```

bit-wise ops:

```
X/\Y, X\/Y, xor(X,Y), \ X (negation), X<<Y, X>>Y (shifts)
```

other:

```
abs(X), sign(X), min(X,Y), max(X,Y),
sin(X), cos(X), tan(X), asin(X), acos(X), atan(X),
atan2(X,Y), sqrt(X), log(X), exp(X), pi
```

Uses of operators

- What are operators good for?
  - to allow usual arithmetic expressions, such as in `X is (Y+3) mod 4`
  - processing of symbolic expressions (such as symbolic derivation)
  - for writing the clauses themselves
    (`:-`, `','`, `;` ... are all standard operators)
    - clauses can be passed as arguments to meta-predicates:
      `asserta( (p(X):-q(X),r(X)) )`
  - to make Prolog data structures look like natural language sentences (controlled English), e.g. Smullyan's island of knights and knaves (knights always tell the truth, knaves always lie):
    We meet natives A and B, A says: one of us is a knave.

    `| ?- solve_puzzle(A says A is a knave or B is a knave).`
  - to make data structures more readable:
    `acid(sulphur, h*2-s-o*4).`

Classical symbolic computation: symbolic derivation

- Write a Prolog predicate which calculates the derivative of a formula built from numbers and the atom `x` using some arithmetic operators.

```
% deriv(Formula, D):  D is the derivative of Formula with respect to x.
deriv(x, 1).
deriv(C, 0) :-                      number(C).
deriv(U+V, DU+DV) :-               deriv(U, DU), deriv(V, DV).
deriv(U-V, DU-DV) :-               deriv(U, DU), deriv(V, DV).
deriv(U*V, DU*V + U*DV) :-         deriv(U, DU), deriv(V, DV).

| ?- deriv(x*x+x, D).      ⟹    D = 1*x+x*1+1 ? ; no

| ?- deriv((x+1)*(x+1), D).
                           ⟹    D = (1+0)*(x+1)+(x+1)*(1+0) ? ; no

| ?- deriv(I, 1*x+x*1+1).  ⟹    I = x*x+x ? ; no

| ?- deriv(I, 2*x+1).      ⟹    no

| ?- deriv(I, 0).          ⟹    no
```

   - Block declarations
   - Further reading

Concatenating lists

- Let L1 $\oplus$ L2 denote the concatenation of L1 and L2,
  i.e. a list consisting of the elements of L1 followed by those of L2.
- Building L1 $\oplus$ L2 in an imperative language
  (A list is either a NULL pointer or a pointer to a head-tail structure):
  - Scan L1 until you reach a tail which is NULL
  - Overwrite the NULL pointer with L2
- If you still need the original L1, you have to copy it, replacing its final NULL
  with L2. A recursive definition of the $\oplus$ (concatenation) function:

  ```
  L1 ⊕ L2 =  if L1 == NULL return L2
             else L3 = tail(L1) ⊕ L2
             return a new list structure whose head is head(L1)
                                       and whose tail is L3
  ```

- Transform the above recursive definition to Prolog:

  ```
  % app0(A, B, C):  the conc(atenation) of A and B is C
  app0([], L2, L2).        % The conc. of [] and L2 is L2.
  app0([X|L1], L2, L) :-   % The conc. of [X|L1] and L2 is L if
      app0(L1, L2, L3),    % the conc. of L1 and L2 is L3 and
      L = [X|L3].          % L's head is X and L's tail is L3.
  ```

Efficient and multi-purpose concatenation

- Drawbacks of the `app0/3` predicate:
    - Uses "real" recursion (needs stack space proportional to length of `L1`)
    - Cannot split lists, e.g. `app0(L1,[3],[1,3])` ⤳ infinite loop
- Apply a generic optimization: eliminate variable assignments
    - Remove goal `Var = T`, and replace occurrences of variable `Var` by `T`
    Not applicable in the presence of disjunctions or if-then-else
- Apply this optimization to the second clause of `app0/3`:
    `app0([X|L1], L2, L) :- app0(L1, L2, L3), L = [X|L3].`
- The resulting code (renamed to `app`, also available as the BIP `append/3`)
    ```
    % app(A, B, C): The conc. of A and B is C, i.e.C = A⊕B
    app([], L2, L2).            % The conc. of [] and L2 is L2.
    app([X|L1], L2, [X|L3]) :- % The conc. of [X|L1] and L2 is [X|L3] if
        app(L1, L2, L3).       % the conc. of L1 and L2 is L3.
    ```
    - This uses constant stack space and can be used for multiple purposes, thanks to Prolog allowing open ended lists
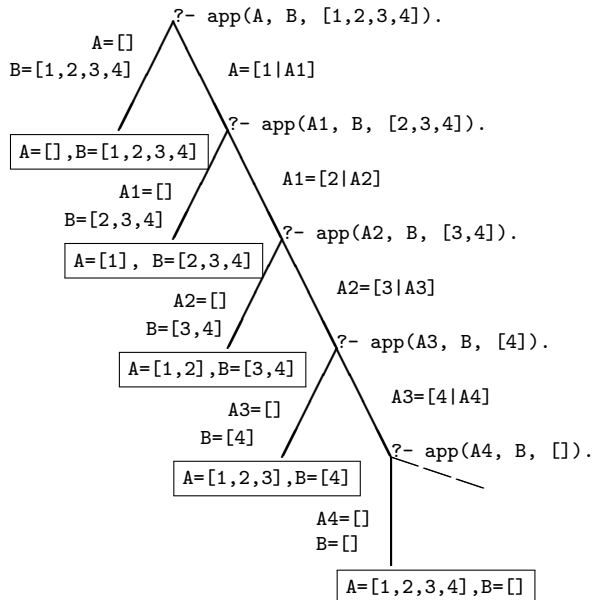

Tail recursion optimization

- Tail recursion optimization (TRO), or more generally last call optimization (LCO) is applicable if
    - the goal in question is the last to be executed in a clause body, and
    - no choice points exist in the given predicate.
- LCO is applicable to the recursive call of `app/3`:

    ```
    app([], L, L).
    app([X|L1], L2, [X|L3]) :- app(L1, L2, L3).
    ```

- This feature relies on open ended lists:
    - It is possible to build a list node *before* building its tail
    - This corresponds to passing to append a pointer to the location where the resulting list should be stored.
- Open ended lists are possible because unbound variables are *first class* objects, i.e. unbound variables are allowed inside data structures. (This type of variable is often called the logic variable).

Splitting lists using `append`

```
% app(L1, L2, L3):
% L1 ⊕ L2 = L3.
app([], L, L).
app([X|L1], L2, [X|L3]) :-
    app(L1, L2, L3).

| ?- app(A, B, [1,2,3,4]).
A = [], B = [1,2,3,4] ? ;
A = [1], B = [2,3,4] ? ;
A = [1,2], B = [3,4] ? ;
A = [1,2,3], B = [4] ? ;
A = [1,2,3,4], B = [] ? ;
no
```

```
?- app(A, B, [1,2,3,4]).
       A=[]
       B=[1,2,3,4]        A=[1|A1]

                          ?- app(A1, B, [2,3,4]).
A=[],B=[1,2,3,4]
                                  A1=[2|A2]
            A1=[]
            B=[2,3,4]     ?- app(A2, B, [3,4]).
   A=[1], B=[2,3,4]
                                  A2=[3|A3]
            A2=[]
            B=[3,4]       ?- app(A3, B, [4]).
   A=[1,2],B=[3,4]
                                  A3=[4|A4]
            A3=[]
            B=[4]         ?- app(A4, B, []).
   A=[1,2,3],B=[4]
                 A4=[]
                 B=[]
            A=[1,2,3,4],B=[]
```

How does the "openness" of arguments affect `append(L1,L2,L3)`?

- `L2` is never decomposed ("looked inside") by append,
  whether it is open ended, does not affect execution
- If `L1` is closed, `append` produces at most one answer

  ```
  | ?- append([a,b], Tail, L).           ⟹  L = [a,b|Tail] ? ; no
  | ?- append([a,b], [c|T], L).          ⟹  L = [a,b,c|T] ?  ; no
  | ?- append([a,b], [c|T], [_,_,d,_]).  ⟹  no
  ```

- If `L3` is closed (of length *n*), `append` produces at most *n* + 1 solutions,
  where `L1` and `L2` are closed lists (also see previous slide):

  ```
  | ?- append(L1,L2,[1,2]).  ⟹  L1=[], L2=[1,2] ? ; L1=[1], L2=[2] ? ;
                                 L1=[1,2], L2=[] ? ; no
  | ?- append([1,2], L, [1,2,3,4,5]).   ⟹  L = [3,4,5] ? ; no
  | ?- append(L1,[4|L2],[1,2,3,4,5]).   ⟹  L1 = [1,2,3],L2 = [5] ? ; no
  | ?- append(L1,[4,2],[1,2,3,4,5]).    ⟹  no
  ```

- The search may be infinite: if **both** the 1st **and** the 3rd arg. is open ended

  ```
  | ?- append([1|L1], [a,b], L3).          ⟹
                L1 = [], L3 = [1,a,b] ? ;
                L1 = [_A], L3 = [1,_A,a,b] ? ;
                L1 = [_A,_B], L3 = [1,_A,_B,a,b] ? ;    ad infinitum :-((((
  | ?- append([1|L1], L2 , [2|L3]).        ⟹  no
  ```

Eight ways of using append(L1,L2,L3) (safe or unsafe)

```
 :- mode append(+, +, +).  % checking if L1 ⊕ L2 = L3 holds
| ?- append([1,2], [3,4], [1,2,3,4]).     ⟹  yes

 :- mode append(+, +, -).  % appending L1 and L2 to obtain L3
| ?- append([1,2], [3,4], L3).            ⟹  L3 = [1,2,3,4] ? ; no

 :- mode append(+, -, +).  % checking if L1 is a prefix of L3, obtaining L2
| ?- append([1,2], L2, [1,2,3,4]).        ⟹  L2 = [3,4] ? ; no

 :- mode append(+, -, -).  % prepending L1 to an open ended L2 to obtain L3
| ?- append([1,2], [3|L2], L3).           ⟹  L3 = [1,2,3|L2] ? ; no

 :- mode append(-, +, +).  % checking if L2 is a suffix of L3 to obtain L1
| ?- append(L1, [3,4], [1,2,3,4]).        ⟹  L1 = [1,2] ? ; no

 :- mode append(-, -, +).  % splitting L3 to L1 and L2 in all possible ways
| ?- append(L1, L2, [1]).  ⟹  L1=[],L2=[1] ? ; L1=[1],L2=[] ? ; no

 :- mode append(-, +, -). (see prev. slide) and :- mode append(-, -, -).
| ?- append(L1, L2, L3).  ⟹  L1=[], L3=L2 ? ; L1=[A], L3=[A|L2] ? ;
                              L1=[A,B], L3=[A,B|L2] ? ...
```

Variation on `append` — appending three lists

- Recall: `append/3` has **finite** search space, if its 1st **or** 3rd arg. is closed.
  `append(L,_,_)` completes in $\leq n + 1$ reduction steps when `L` has length n

- Let us define `append(L1,L2,L3,L123)`: $L1 \oplus L2 \oplus L3 = L123$. First attempt:
  ```
  append(L1, L2, L3, L123) :-
          append(L1, L2, L12), append(L12, L3, L123).
  ```

  - Inefficient: `append([1,...,100],[1,2,3],[1], L)` – 203 and not 103 steps...
  - Not suitable for splitting lists – may create an infinite choice point

- An efficient version, suitable for splitting a given list to three parts:
  ```
  % L1 ⊕ L2 ⊕ L3 = L123,
  % where either both L1 and L2 are closed, or L123 is closed.
  append(L1, L2, L3, L123) :-
          append(L1, L23, L123), append(L2, L3, L23).
  ```

  - `L3` can be open ended or closed, it does not matter
  - Note that in the first `append/3` call either `L1` or `L123` is closed.
    If `L1` is closed, the first `append/3` produces an open ended list:
    ```
    | ?- append([1,2], L23, L123).        ⟹        L123 = [1,2|L23]
    ```

The BIP length/2 – length of a list

- length(?List, ?N): list List is of length N

  ```
  | ?- length([4,3,1], Len).          Len = 3 ? ;
                                       no
  | ?- length(List, 3).               List = [_A,_B,_C] ? ;
                                       no
  | ?- length([[4,1,3],[2,8,7]], Len). Len = 2 ? ;
                                       no

  | ?- length(L, N).                  L = [], N = 0 ? ;
                                       L = [_A], N = 1 ? ;
                                       L = [_A,_B], N = 2 ? ;
                                       L = [_A,_B,_C], N = 3 ? ...
  ```

- length/2 has an infinite search space if the first argument is an open ended list and the second is a variable.

Appending a list of lists

- Library `lists` contains a predicate `append/2`
  see e.g. `https://www.swi-prolog.org/search?for=append%2F2`
  ```
  % append(LL, L): LL is a closed list of lists.
  %                L is the concatenation of the elements of LL.
  ```
- Conditions for safe use (finite search space):
  - Each element of `LL` is a closed list
    ```
    | ?- append([[1,2],[3],[4,5]], L).  ⟹  L = [1,2,3,4,5] ? ; no
    ```
  - `L` is a closed list
    ```
    | ?- append([L1,L2,L3], [1,2]), L1 \= [],
        ⟹                   L1 = [1],    L2 = [],    L3 = [2] ? ;
                            L1 = [1],    L2 = [2],   L3 = [] ? ;
                            L1 = [1,2],  L2 = [],    L3 = [] ? ; no
    ```
- Finding a sublist matching a given pattern:
  ```
  | ?- Pattern = [_A,_,_A], append([_Pref,Pattern,_],[1,2,3,2,1,2]),
      length(_Pref, Index).            % obtain the index of the Pattern
  Pattern = [2,3,2], Index = 1 ? ;     % Index is zero-based
  Pattern = [2,1,2], Index = 3 ? ;  no
  ```

Finding list elements – BIP `member/2`

```
% member(E, L): E is an element of list L
member(Elem, [Elem|_]).              member1(Elem, [Head|Tail]) :-
member(Elem, [_|Tail]) :-            (    Elem = Head
    member(Elem, Tail).              ;    member1(Elem, Tail)
                                     ).
```

- Mode `member(+,+)` – checking membership

  | ?- member(2, [2,1,2]). $\implies$ yes   BUT
  | ?- member(2, [2,1,2]), R=yes. $\implies$ R = yes ? ; R = yes ? ; no

- Mode `member(-,+)` – enumerating list elements:

  | ?- member(X, [1,2,3]). $\implies$ X = 1 ? ; X = 2 ? ; X = 3 ? ; no
  | ?- member(X, [1,2,1]). $\implies$ X = 1 ? ; X = 2 ? ; X = 1 ? ; no

- Finding common elements of lists – with both above modes:

  | ?- member(X, [1,2,3]),
      member(X, [5,4,3,2,3]). $\implies$ X = 2 ? ; X = 3 ? ; X = 3 ? ; no

- Mode `member(+,-)` – making a term an element of a list (infinite choice):

  | ?- member(1, L). $\implies$ L = [1|_A] ? ; L = [_A,1|_B] ? ;
                                        L = [_A,_B,1|_C] ? ; ...

- The search space of `member/2` is **finite**, if the 2nd argument is closed.

Reversing lists

- Naive solution (quadratic in the length of the list)
  ```
  % nrev(L, R): List R is the reverse of list L.
  nrev([], []).
  nrev([X|L], R) :-
      nrev(L, RL),
      append(RL, [X], R).
  ```
- A solution which is linear in the length of the list
  ```
  % reverse(L, R): List R is the reverse of list L.
  reverse(L, R) :-  revapp(L, [], R).

  % revapp(L1, L2, R): The reverse of L1 prepended to L2 gives R.
  revapp([], R, R).
  revapp([X|L1], L2, R) :-
      revapp(L1, [X|L2], R).
  ```
- In SICStus 4 `append/3` is a BIP, `reverse/2` is in library `lists`
- To load the library place this directive in your program file:
  ```
  :- use_module(library(lists)).
  ```

append and revapp — building lists forth and back (ADVANCED)

- Prolog

```
app([], L, L).
app([X|L1], L2, [X|L3]) :-
    app(L1, L2, L3).
```

```
revapp([], L, L).
revapp([X|L1], L2, L3) :-
    revapp(L1, [X|L2], L3).
```

- C++

```
struct link   { link *next;
                char elem;
                link(char e): elem(e) {}   };
typedef link *list;
```

```
list app(list L1, list L2)
{ list L3, *lp = &L3;
  for (list p=L1; p; p=p->next)
  { list newl = new link(p->elem);
    *lp = newl; lp = &newl->next;
  }
  *lp = L2;  return L3;
}
```

```
list revapp(list L1, list L2)
{ list l = L2;
  for (list p=L1; p; p=p->next)
  { list newl = new link(p->elem);
    newl->next = l; l = newl;
  }
  return l;
}
```

Generalization of `member`: `select/3` – defined in library `lists`

```
% select(E, List, Rest):  Removing E from List results in list Rest.
select(E, [E|Rest], Rest).      % The head is removed, the tail remains.
select(E, [X|Tail], [X|Rest]):- % The head remains,
    select(E, Tail, Rest).      % the element is removed from the Tail.
```

Possible uses:

```
| ?- select(1, [2,1,3,1], L).          % Remove a given element
     L = [2,3,1] ? ; L = [2,1,3] ? ; no
| ?- select(X, [1,2,3], L).            % Remove an arbitrary element
     L=[2,3], X=1 ? ;  L=[1,3], X=2 ? ;    L=[1,2], X=3 ? ; no
| ?- select(3, L, [1,2]).              % Insert a given element!
     L = [3,1,2] ? ; L = [1,3,2] ? ; L = [1,2,3] ? ; no
| ?- select(3, [2|L], [1,2,7,3,2,1,8,9,4]).
     no                                % Can one remove 3 from [2|L]
                                       % to obtain [1,...]?
| ?- select(1, [X,2,X,3], L).
     L = [2,1,3], X = 1 ? ; L = [1,2,3], X = 1 ? ; no
```

- The search space of `select/3` is **finite**, if the 2nd **or** the 3rd arg. is closed.

Permutation of lists – two solutions (ADVANCED)

`perm(+List, ?Perm)`: The list `Perm` is a permutation of `List`

```
perm0([], []).
perm0(L, [H|P]) :-
    select(H, L, R),        % Select H from L as the head of the output, R remaining.
    perm0(R, P).            % Permute R to become P, the tail of the output list.

| ?- perm0([a,b,c], L).
                    L = [a,b,c] ? ; L = [a,c,b] ? ; L = [b,a,c] ? ;
                    L = [b,c,a] ? ; L = [c,a,b] ? ; L = [c,b,a] ? ; no
perm1([], []).
perm1([H|T], P) :-
    perm1(T, P1),           % Permute T, the tail of the input list, obtaining P1.
    select(H, P, P1).       % Insert H, the head of the input list, into an arbitrary
    % mode:+  -  +          % position within P1 to obtain the output list, P.
| ?- perm1([a,b,c], L).
                    L = [a,b,c] ? ; L = [b,a,c] ? ; L = [b,c,a] ? ;
                    L = [a,c,b] ? ; L = [c,a,b] ? ; L = [c,b,a] ? ; no
```

- `perm` is symmetric, so the two predicates have the same meaning (WHAT)
- But the second variant is much faster!

Contents

Principles of Prolog term ordering $\prec$

Different kinds ordered left-to-right:

$$\texttt{var} \prec \texttt{float} \prec \texttt{integer} \prec$$
$$\prec \texttt{atom} \prec \texttt{compound}$$

- Ordering of variables: system dependent
- Ordering of floats and integers: usual ($x \prec y \Leftrightarrow x < y$)
- Ordering of atoms: lexicographical (abc$\prec$abcd, abcv$\prec$abcz)
- Compound terms: $\texttt{name}_a(a_1, \ldots, a_n) \prec \texttt{name}_b(b_1, \ldots, b_m)$ iff
  1. $n < m$, e.g. p(x,s(u,v,w)) $\prec$ a(b,c,d), or
  2. $n = m$, and $\texttt{name}_a \prec \texttt{name}_b$ (lexicographically), e.g. a(x,y) $\prec$ p(b,c), or
  3. $n = m$, $\texttt{name}_a = \texttt{name}_b$, and for the first i where $a_i \neq b_i$, $a_i \prec b_i$,
     e.g. r(1,u+v,3,x) $\prec$ r(1,u+v,5,a)

Built-in predicates for comparing Prolog terms

- Comparing two Prolog terms:

Goal	holds if
`Term1 == Term2`	$\text{Term1} \nprec \text{Term2} \wedge \text{Term2} \nprec \text{Term1}$
`Term1 \== Term2`	$\text{Term1} \prec \text{Term2} \vee \text{Term2} \prec \text{Term1}$
`Term1 @< Term2`	$\text{Term1} \prec \text{Term2}$
`Term1 @=< Term2`	$\text{Term2} \nprec \text{Term1}$
`Term1 @> Term2`	$\text{Term2} \prec \text{Term1}$
`Term1 @>= Term2`	$\text{Term1} \nprec \text{Term2}$

- The comparison predicates are not purely logical:

  `| ?- X @< 3, X = 4. $\implies$ X = 4`

  `| ?- X = 4, X @< 3. $\implies$ no`

  as they rely on the current instantiation of their arguments
- Comparison uses, of course, the canonical representation:

  `| ?- [1, 2, 3, 4] @< s(1,2,3). $\implies$ **yes**`
- BIP `sort(L, S)` sorts (using `@<`) a list `L` of arbitrary Prolog terms, removing duplicates (w.r.t. `==`). Thus the result is a strictly increasing list `S`.

  `| ?- sort([1, 2.0, s(a,b), s(a,c), s, X, s(Y), t(a), s(a), 1, X], L).`
  `L = [X,2.0,1,s,s(Y),s(a),t(a),s(a,b),s(a,c)] ?`

Equality-like Prolog predicates – a summary

Recall: a Prolog term is *ground* if it contains no unbound variables

- U = V: U unifies with V
  No errors. May bind vars.

```
| ?- X = 1+2.      ⟹   X = 1+2
| ?- 3 = 1+2.      ⟹   no
```

- U == V: U is identical to V, i.e.
  $U=V$ succeeds with no bindings
  No errors, no bindings.

```
| ?- X == 1+2.      ⟹   no
| ?- 3 == 1+2.      ⟹   no
| ?- +(X,Y)==X+Y    ⟹   yes
```

- U =:= V: The value of U is
  arithmetically equal to that of V.
  No bindings. Error if U or V is not
  a (ground) arithmetic expression.

```
| ?- X =:= 1+2.     ⟹   error
| ?- 1+2 =:= X.     ⟹   error
| ?- 2+1 =:= 1+2.   ⟹   yes
| ?- 3.0 =:= 1+2.   ⟹   yes
```

- U is V: U is unified with the
  value of V.
  Error if V is not a (ground)
  arithmetic expression.

```
| ?- X is 1+2.      ⟹   X = 3
| ?- 3.0 is 1+2.    ⟹   no
| ?- 1+2 is X.      ⟹   error
| ?- 3 is 1+2.      ⟹   yes
| ?- 1+2 is 1+2.    ⟹   no
```

Nonequality-like Prolog predicates – a summary

- Nonequality-like Prolog predicates **never** bind variables.

- U \= V: U does not unify with V.
  No errors.

  | ?- X \= 1+2. $\implies$ no
  | ?- X \= 1+2, X = 1. $\implies$ no
  | ?- X = 1, X \= 1+2. $\implies$ yes
  | ?- +(1,2) \= 1+2. $\implies$ no

- U \== V: U is not identical to V.
  No errors.

  | ?- X \== 1+2. $\implies$ yes
  | ?- X \== 1+2, X=1+2. $\implies$ yes
  | ?- 3 \== 1+2. $\implies$ yes
  | ?- +(1,2)\==1+2 $\implies$ no

- U =\= V: The values of the
  arithmetic expressions U and V
  are different.
  Error if U or V is not a (ground)
  arithmetic expression.

  | ?- X =\= 1+2. $\implies$ **error**
  | ?- 1+2 =\= X. $\implies$ **error**
  | ?- 2+1 =\= 1+2. $\implies$ no
  | ?- 2.0 =\= 1+1. $\implies$ no

(Non)equality-like Prolog predicates – examples

U	V	Unification		Identical terms		Arithmetic		
		U = V	U \= V	U == V	U \== V	U =:= V	U =\= V	U is V
1	2	*no*	yes	*no*	yes	*no*	yes	*no*
a	b	*no*	yes	*no*	yes	error	error	error
1+2	+(1,2)	yes	*no*	yes	*no*	yes	*no*	*no*
1+2	2+1	*no*	yes	*no*	yes	yes	*no*	*no*
1+2	3	*no*	yes	*no*	yes	yes	*no*	*no*
3	1+2	*no*	yes	*no*	yes	yes	*no*	yes
X	1+2	X=1+2	*no*	*no*	yes	error	error	X=3
X	Y	X=Y	*no*	*no*	yes	error	error	error
X	X	yes	*no*	yes	*no*	error	error	error

Legend: yes – success; *no* – failure.

3 Declarative Programming with Prolog

Higher order programming: using predicates as arguments

- Example: collect all nonzero elements of a list
  ```
  % nonzero_elems(Xs, Ys): Ys is a list of all nonzero elements of Xs
  nonzero_elems([], []).
  nonzero_elems([X|Xs], Ys) :-
      (   0 \= X -> Ys = [X|Ys1]
      ;   Ys = Ys1
      ),
      nonzero_elems(Xs, Ys1).
  ```
- Generalize to a predicate where the condition is given as an argument
  ```
  % include(Pred, Xs, Ys): Ys = list of elems of Xs that satisfy Pred
  include(_Pred, [], []).
  include(Pred, [X|Xs], Ys) :-
      (   call(Pred, X) -> Ys = [X|Ys1]
      ;   Ys = Ys1
      ),
      include(Pred, Xs, Ys1).
  ```
- Specialize include for collecting nonzero elements:
  ```
  nonz(X) :- 0 \= X.
  nonzero_elems(L, L1) :- include(nonz, L, L1).
  ```

Higher order predicates

- A higher order predicate (or meta-predicate) is a predicate with an argument which is interpreted as a goal, or a *partial goal*
- A partial goal is a goal with the last few arguments missing
    - e.g., a predicate name is a partial goal
      (hence variable name Pred is often used for partial goals)
- The BIP call(PG, X), where PG is a partial goal, adds X as the last argument to PG and executes this new goal:
    - if PG is an atom ⇒ it calls PG(X), e.g. call(number, X) ≡ number(X)
    - if PG is a compound Pred(A₁,...,Aₙ) ⇒ it calls Pred(A₁,...,Aₙ,X),
      e.g. call(\=(0), X) ≡ \=(0,X) ≡ 0 \= X
- Predicate include(Pred, L, FL) is in library(lists)

```
| ?- L=[1,2,a,X,b,0,3+4],
     include(number, L, Nums).  % Nums = { x ∈ L | number(x) }
Nums = [1,2,0] ? ; no
| ?- L=[0,2,0,3,-1,0],
     include(\=(0), L, NZs).    % NZs = { x ∈ L | \=(0,x) }
NZs = [2,3,-1] ?
```

Calling predicates with additional arguments

- Recall: a callable term is a compound or atom.
- There is a group of built-in predicates call/*N*
    - call(Goal): invokes Goal, where Goal is a callable term
    - call(PG, A): Adds A as the last argument to PG, and invokes it.
    - call(PG, A, B): Adds A and B as the last two args to PG, invokes it.
    - call(PG, A_1, ..., A_n): Adds A_1, ..., A_n as the last *n* arguments to PG, and invokes the goal so obtained.
- PG is a partial goal, to be extended with additional arguments before calling. It has to be a callable term.

```
even(X) :- X mod 2 =:= 0.
| ?- include(even, [1,3,2,9,6,4,0], FL).
                                    ⟹      FL = [2,6,4,0] ; no
divisible_by(N, X) :- X mod N =:= 0.
| ?- include(divisible_by(3), [1,3,2,9,6,4,0], FL).
                                    ⟹      FL = [3,9,6,0] ; no
```

- In descriptions we often abbreviate call(PG, A_1, ..., A_n) to PG(A_1, ..., A_n)

An important higher order predicate: `maplist/3`

- `maplist(:PG, ?L, ?ML)`: for each x element of L and the corresponding Y element of ML, `call(PG, X, Y)` holds, where PG is a partial goal requiring two additional arguments
- Annotation "`:`" (as in `:PG` above) marks a meta argument, i.e. a term to be interpreted as a goal or a partial goal

```
maplist(_PG, [], []).
maplist(PG, [X|Xs], [Y|Ys]) :-
    call(PG, X, Y),
    maplist(PG, Xs, Ys).

| ?- maplist(reverse, [[1,2],[3,4]], LL).  ⟹  LL = [[2,1],[4,3]] ? ; no

square(X, Y) :- Y is X*X.

mult(N, X, NX) :- NX is N*X.

| ?- maplist(square, [1,2,3,4], L).   ⟹  L = [1,4,9,16] ? ; no
| ?- maplist(mult(2), [1,2,3,4], L).  ⟹  L = [2,4,6,8] ? ; no
| ?- maplist(mult(-5), [1,2,3], L).   ⟹  L = [-5,-10,-15] ? ; no
```

Variants of `maplist`

In SICStus, `maplist` can also be used with 2 and 4 arguments

- `maplist(:Pred, +Xs)` is true if for each *x* element of `Xs`, `Pred(x)` holds.
- Example: check if a condition holds for all elements of a list
  ```
  all_positive(Xs) :-          % all elements of Xs are positive
      maplist(<(0), Xs).       % ∀ X ∈ Xs, <(0, X), i.e. 0 < X holds
  ```
- `maplist(:Pred, ?Xs, ?Ys, ?Zs)` is true when `Xs`, `Ys`, and `Zs` are lists of equal length, and `Pred(X, Y, Z)` is true for corresponding elements `X` of `Xs`, `Y` of `Ys`, and `Z` of `Zs`. At least one of `Xs`, `Ys`, `Zs` has to be a closed list.
- Example: add two vectors
  ```
  add_vectors(VA, VB, VC) :-
      maplist(plus, VA, VB, VC).          plus(A, B, C) :- C is A+B.
  | ?- add_vectors([10,20,30], [3,2,1], V). ⟹  V = [13,22,31] ? ; no
  ```
- The implementation of `maplist/4` (easy to generalize :-):
  ```
  maplist(_PG, [], [], []).
  maplist(PG, [X|Xs], [Y|Ys], [Z|Zs]) :-
      call(PG, X, Y, Z), maplist(PG, Xs, Ys, Zs).
  ```

Another important higher order predicate: `scanlist` (SWI: `foldl`)

- Example: `plus(A, S0, S) :- S is S0+A.`

  `| ?- scanlist(plus, [1,3,5], 0, Sum).` $\implies$ `Sum = 9 ? ; no`
  `% 0+1+3+5 = 9`

  This executes as: `plus(0, 1, S₁), plus(S₁, 3, S₂), plus(S₂, 5, Sum).`

- In general: `scanlist(acc, [E₁,E₂,...,Eₙ], S₀, Sₙ)` is expanded as:
  `acc(S₀, E₁, S₁), acc(S₁, E₂, S₂), ..., acc(S_{n-1}, Eₙ, Sₙ)`

- `scanlist(:PG, ?L, ?Init, ?Final)`:
  - `PG` represents the above accumulating predicate `acc`
  - `scanlist` applies the `acc` predicate repeatedly, on all elements of list `L`, left-to-right, where `Init = S₀` and `Final = Sₙ`.

- For processing two lists (of the same length), use `scanlist/5`, e.g.

  `prodsum(A, B, PS0, PS) :- PS is PS0 + A*B.`

  `scalar_product(As, Bs, SP) :- scanlist(prodsum, As, Bs, 0, SP).`
  `| ?- scalar_product([1,0,2], [3,4,5], SP).` $\implies$ `SP = 13 ? ; no`

- In SICStus, there is also a `scanlist/6` predicate, for processing 3 lists

Contents

All solutions built-in predicates – introduction

- All solution BIPs are higher order predicates analogous to list comprehensions in Haskell, Python, etc.
- There are three such predicates: `findall/3` (the simplest), `bagof/3` and `setof/3`; having the same arguments, but somewhat different behavior
- Examples for `findall/3`:

```
| ?- findall(X, (member(X,   [1,7,8,3,2,4]), X > 3),  L).
%            {X |        X ∈ {1,7,8,3,2,4},  X > 3} = L
             ⟹   L = [7,8,4] ? ; no
| ?- findall(X, (member(X,   [1,7,8,3,2,4]), X > 8),  L).
%            {X |        X ∈ {1,7,8,3,2,4},  X > 8} = L
             ⟹   L = [] ? ; no
| ?- findall(X-Y, (between(1, 3, X), between(1, X, Y)),  L).
%            {X-Y |        1 ≤ X ≤ 3,        1 ≤ Y ≤ X } = L
             ⟹   L = [1-1,2-1,2-2,3-1,3-2,3-3] ? ; no
```

Recall: `between(+N, +M, ?X)` enumerates in `X` the integers `N`, `N+1`, ..., `M`. In SICStus, it requires loading `library(between)`.

Finding all solutions: the BIP `findall(?Templ, :Goal, ?L)`

Approximate meaning: `L` is a list of `Templ` terms for each solution of `Goal`

The execution of the BIP `findall/3` (procedural semantics):

- Interpret term `Goal` as a goal, and call it
- For each solution of `Goal`:
    - store a *copy* of `Templ` (copy $\Longrightarrow$ replace vars in `Templ` by new ones)
      Note that copying requires time proportional to the size of `Templ`
    - continue with failure (to enumerate further solutions)
- When there are no more solutions (`Goal` fails)
    - collect the stored `Templ` values into a list, unify it with `L`.
- When a solution contains (possibly multiple instances of) a variable (e.g. `A`),
  then each of these will be replaced by a single new variable (e.g. `_A`):

  ```
  | ?- findall(T, member(T, [A-A,B-B,A]), L).
                          ⟹ L= [_A-_A,_B-_B,_C] ? ; no
  ```

All solutions: the BIP `bagof(?Templ, :Goal, ?L)`

- Exactly the same arguments as in `findall/3`.
  `bagof/3` is the same as `findall/3`, except when there are unbound
  variables in `Goal` which do not occur in `Templ` (so called free variables)
  ```
  % emp(Er, Ee): employer Er employs employee Ee.
  emp(a,b).   emp(a,c).   emp(b,c).   emp(b,d).
  | ?- findall(E, emp(R, E), Es). % Es ≡ the list of all employees
      ⟹  Es = [b,c,c,d] ? ; no    i.e. Es = {E | ∃ R. (R  employs  E)}
  ```
- `bagof` does not treat free vars as existentially quantified. Instead it
  enumerates all possible values for the free vars (all employers) and for
  each such choice it builds a separate list of solutions:
  ```
  | ?- bagof(E,emp(R,E),Es). % Es ≡ list of Es employed by any possible R.
          ⟹   R = a, Es = [b,c] ? ;
          ⟹   R = b, Es = [c,d] ? ; no
  ```
- Use operator `^` to achieve existential quantification in `bagof`:
  ```
  | ?- bagof(E, R^emp(R, E), Es). %  Collect Es for which ∃R.emp(R, E)
              ⟹  Es = [b,c,c,d] ? ; no
  ```
- `bagof` preserves variables (but it is slower than `findall` :-( ):
  ```
  | ?- bagof(T, member(T, [A-A,B-B,A]), L). ⟹ L = [A-A,B-B,A] ? ; no
  ```

All solutions: the BIP `setof/3`

- `setof(?Templ, :Goal, ?List)`
- The execution of the procedure:
    - same as: `bagof(Templ, Goal, L0), sort(L0, List)`
    - recall: `sort(+L, ?SL)` is a built-in predicate which sorts `L` using the `@<` built-in predicate removes duplicates and unifies the result with `SL`
- Example:

  ```
  graph([a-b,a-c,b-c,c-d,b-d]).
  ```
  % Graph has a node V.
  ```
  has_node(Graph, V) :- member(A-B, Graph), ( V = A ; V = B).
  ```
  % The set of nodes of G is Vs.
  ```
  graph_nodes(G, Vs) :- setof(V, has_node(G, V), Vs).
  ```
  ```
  | ?- graph(_G), graph_nodes(_G, Vs). ⟹  Vs = [a,b,c,d] ? ; no
  ```

Contents

Causes of inefficiency – preview

- Unnecessary choice points (ChPs) waste both time and space
  Recursive definitions often leave choice points behind on exit, e.g.:
  - *% fact0(+N, ?F): F = N!.*
    ```
    fact0(0, 1).
    fact0(N, F) :- N > 0, N1 is N-1, fact0(N1, F1), F is N*F1.
    ```
  - Remedy: use if-then-else or the cut BIP (coming soon)
  - *% last0(L, E): The last element of L is E.*
    ```
    last0([E], E).
    last0([_|L], E) :- last0(L, E).
    ```
  - Remedy: rewrite to make use of indexing (or cut, or if-then-else)
- General recursion, as opposed to tail recursion
  As an example, see the `fact0/2` predicate above
  Remedy: re-formulate to a tail recursive form, using accumulators

The cut – the BIP underlying if-then-else and negation

- The cut, denoted by `!`, is a BIP with no arguments, i.e. its functor is `!/0`.
- Execution: the cut always succeeds with these two side effects:
    - Restrict to the first solution of a goal:
      Remove all choice points created within the goal(s) preceding the `!`.
      ```
      % is_a_parent(+P): check if a given P is a parent.
      is_a_parent(P) :- has_parent(_, P), !.
      ```
    - Commit to the clause containting the cut:
      Remove the choice of any further clauses in the current predicate.
      ```
      fact1(0, F) :- !, F = 1.  % Assign output vars only after the cut,
                                % both for correctness and efficiency
      fact1(N, F) :- N > 0, N1 is N-1, fact1(N1, F1), F is N*F1.
      ```
- Definition: if `q :- ..., p, ....` then
  the parent goal of `p` is the goal matching the clause head `q`
- Effects of cut in the search tree: removes all choice points up to and
  including the node labelled with the parent goal of the cut.
- In the procedure box model: Fail port of cut $\Longrightarrow$ Fail port of parent goal

How does "cut" prune the search tree – an example

```
a(X, Y) :- b(X), c(X, Y).                  b(s(1)).
a(X, Y) :- d(X, Y).                        b(s(2)).

c(s(X), Y) :- Y is X+10.                   d(s(3), 30).
c(s(X), Y) :- Y is X+20.                   d(t(4), 40).

a_cut(X, Y) :- b(X), !, c(X, Y).
a_cut(X, Y) :- d(X, Y).

test(Pred, X, Res) :-
    findall(X-Y, call(Pred, X, Y), Res).
```

Sample runs:

```
| ?- test(a,     s(_), Res).  ⟹   Res = [s(1)-11,s(1)-21,s(2)-12,
                                          s(2)-22,s(3)-30] ?
| ?- test(a,     t(_), Res).  ⟹   Res = [t(4)-40] ?
| ?- test(a_cut, s(_), Res).  ⟹   Res = [s(1)-11,s(1)-21] ?
| ?- test(a_cut, s(3), Res).  ⟹   Res = [s(3)-30] ?
| ?- test(a_cut, t(_), Res).  ⟹   Res = [t(4)-40] ?
```

Avoid leaving unnecessary choice points

- Add a cut if you know that remaining branches are doomed to fail. (These are so called green cuts, which do not remove solutions.)
- Example of a green cut:

```prolog
% last1(L, E): The last element of L is E.
last1([E], E)    :- !.
last1([_|L], E) :- last1(L, E).
```

In the absence of the cut, the goal `last1([1], X)` will return the answer `X = 1`, and leave a choice point. When this choice point is explored `last1([], X)` will be called which will always fail.

- Instead of a cut, one can use if-then-else:

```prolog
last2([E|L], X) :- ( L == [] -> X = E
                   ; last2(L, X)
                   ).

fact2(N, F) :-     ( N == 0 -> F = 1
                   ; N > 0, N1 is N-1, fact2(N1, F1), F is N*F1
                   ).
```

Avoid leaving unnecessary choice points – indexing

- Recall a simple example predicate, summing a binary tree:

  ```
  % tree_sum(+Tree, ?Sum):
  % Sum is the sum of integers in the leaves of Tree.
  tree_sum(leaf(Value), Value).        1st head arg's functor: leaf/1
  tree_sum(node(Left, Right), S) :-    1st head arg's functor: node/2
          tree_sum(Left, S1), tree_sum(Right, S2), S is S1+S2.
  ```

- Indexing groups the clauses of a predicate based on the outermost functor of (usually) the first argument.

- The compiler generates code (using hashing) to select the subset of clauses that corresponds to this outermost functor.

- If the subset contains a single clause, no choicepoint is created. (This is the case in the above example.)

SICStus specific: avoid choice points in if-then-else (ADVANCED)

- Consider an if-then-else goal of the form: (cond -> then ; else).
- Before cond, a ChP is normally created (removed at -> or before else).
- In **SICStus Prolog** no choice points are created, if cond only contains:
  - arithmetical comparisons (e.g., <, =<, =:=); and/or
  - built-in predicates checking the term type (e.g., atom, number); and/or
  - general comparison operators (e.g., @<, @=<, ==).
- Analogously, no ChPs are made for head :- cond, !, then.,
  if all arguments of head are distinct variables, and cond is just like above.
- Further improved variants of fact2 and last2 with no ChPs created:

```
fact3(N, F) :-      ( N =:= 0 -> F = 1      % used to be N = 0
                    ; N > 0, N1 is N-1, fact(N1, F1), F is N*F1
                    ).

last3([E|L], X) :- ( L == [] -> X = E      % used to be L = []
                    ; last3(L, X)
                    ).
```

Indexing – an introductory example

- A sample (meaningless) program to illustrate indexing.

```
p(0, a).        /* (1) */              q(1).
p(X, t) :- q(X). /* (2) */             q(2).
p(s(0), b).     /* (3) */
p(s(1), c).     /* (4) */
p(9, z).        /* (5) */
```

- For the call `p(A, B)`, the compiler produces a case statement-like construct, to determine the list of applicable clauses:

(VAR)	if `A` is a variable:	(1) (2) (3) (4) (5)
(0/0)	if `A = 0` (`A`'s main functor is 0/0):	(1) (2)
(s/1)	if `A`'s main functor is `s/1`:	(2) (3) (4)
(9/0)	if `A = 9`:	(2) (5)
(OTHER)	in all other cases:	(2)

- Example calls (do they create and leave a choice point?)
  - `p(1, Y)` takes branch (OTHER), does not create a choice point.
  - `p(s(1), Y)` takes branch (s/1), creates a choice point,
    but removes it and exits without leaving a choice point.
  - `p(s(0), Y)` takes branch (s/1), and exits leaving a choice point.

Indexing

- Indexing improves the efficiency of Prolog execution by
  - speeding up the selection of clauses matching a particular call;
  - using a compile-time grouping of the clauses of the predicate.
- Most Prolog systems, including SICStus, use only the main (i.e. outermost) functor of the *first* argument for indexing, which is
  - C/0, if the argument is a constant (atom or number) C;
  - R/N, if the argument is a compound with name R and arity N;
  - undefined, if the argument is a variable.

Implementing indexing

- Compile-time: collect the set of (outermost) functors of nonvar terms occurring as first args, build the case statement (see prev. slide)
- Run-time: select the relevant clause list using the first arg. of the call. This is practically a constant time operation, as it uses *hashing*.
  - If the clause list is a singleton, *no choice point* is created.
  - Otherwise a choice point *is* created, which will be removed before entering the last branch.

Getting the most out of indexing

- Get deep indexing through helper predicates (rewrite `p/2` to `q/2`):

```
p(0, a).              q(0, a).              q_aux(0, b).
p(s(0), b).    ⟹     q(s(X), Y) :-         q_aux(1, c).
p(s(1), c).               q_aux(X, Y).
p(9, z).              q(9, z).
```

Pred. `q(X,Y)` will not create choice points if `X` is ground.

- Indexing does not deal with arithmetic comparisons
    - E.g., `N = 0` and `N > 0` are not recognized as mutually exclusive.
- Indexing and lists
    - Putting the (input) list in the first argument makes indexing work.
    - Indexing distinguishes between `[]` and `[...|...]`
      (resp. functors: `'[]'/0` and `'.'/2`).
    - For proper lists, the order of the two clauses is not relevant
    - For use with open ended lists: put the clause for `[]` first, to avoid an
      infinite loop (an infinite choice may still remain)

Indexing list handling predicates

- Predicate `app/3` creates no choice points
  if the first argument is a proper list:
  ```
  % app(L1, L2, L3): L1 ⊕ L2 = L3.            % 1st arg funct:
  app([], L, L).                              % []/0
  app([X|L1], L2, [X|L3]) :-                  % . /2
      app(L1, L2, L3).
  ```
- The same is true for `revapp/3`:
  ```
  % revapp(L1, L2, L3):
  % appending the reverse of L1 and L2 gives L3
  revapp([], L, L).                           % []/0
  revapp([X|L1], L2, L3) :-                   % . /2
      revapp(L1, [X|L2], L3).
  ```

Indexing list handling predicates, cont'd

- Getting the last element of a list: `last0/2` leaves a choice point.

  ```
  % last0(L, E): The last element of L is E.
  last0([H], H).                                    % . /2
  last0([_|T], E) :-      last0(T, E).              % . /2
  ```

- The variant `last4/2` uses a helper predicate, creates no choice points:

  ```
  last4([H|T], E) :-      last4(T, H, E).                          (*)
  % last4(T, H, E): The last element of [H|T] is E.
  last4([], E, E).                                  % []/0
  last4([H|T], _, E) :-  last4(T, H, E).            % . /2
  ```

- `member0/2` (as defined earlier) always leaves a choice point.

  ```
  % member0(E, L): E is an element of L.
  member0(E, [E|_T]).                               % VAR
  member0(E, [_H|T]) :-  member0(E, T).             % VAR
  ```

- Write the head comment and the clauses of `member1/3`, so that `member1/2` leaves no choice point when the last element of a (proper) list is returned.

  ```
  member1(E, [H|T]) :-  member1(T, H, E).           % cf. (*)
  % member1(T, H, E): ...
  ```

Tail recursion

- In general, recursion is expensive both in terms of time and space.
- The special case of tail recursion can be compiled to a loop. Conditions:
    1. the recursive call is the last to be executed in the clause body, i.e.:
        - it is textually the last subgoal in the body; or
        - the last subgoal is a disjunction/if-then-else, and the recursive call is the last in one of the branches
    2. no ChPs left in the predicate when the recursive call is reached
- Example

```
% all_pos(+L): all elements of number list L are positive.
all_pos([]).
all_pos([X|L]) :-
    X > 0, all_pos(L).
```

- *Tail recursion optimization, TRO*: the memory allocated by the clause is freed **before** the last call is executed.
- This optimization is performed not only for recursive calls but for the **last** calls in general (*last call optimization, LCO*).

Making a predicate tail recursive – accumulators

- Example: the sum of a list of numbers. The left recursive variant:

  % sum0(+List, -Sum): the sum of the elements of List is Sum.
  ```
  sum0([], 0).
  sum0([X|L], Sum) :- sum0(L, Sum0), Sum is Sum0+X.
  ```

  Note that $sum0([a_1,\ldots, a_n], S) \implies S = 0+a_n+\ldots +a_1$ (right to left)

- For TRO, define a helper pred, with an arg. storing the "sum so far":

  % sum(+List, +Sum0, -Sum):
  % ($\sum$ List) + Sum0 = Sum, i.e. $\sum$ List = Sum−Sum0.
  ```
  sum([], Sum, Sum).
  sum([X|L], Sum0, Sum) :-
      Sum1 is Sum0+X,     % Increment the ''sum so far''
      sum(L, Sum1, Sum). % recurse with the tail and the new sum so far
  ```

- Arguments Sum0 and Sum form an accumulator pair: Sum0 is an intermediate while Sum is the final value of the accumulator.
  The initial value is supplied when defining sum/2:

  % sumlist(+List, ?Sum): $\sum$ List = Sum. Available from library(lists).
  ```
  sumlist(List, Sum) :-  sum(List, 0, Sum).
  ```

  Note that $sumlist([a_1,\ldots, a_n], S) \implies S = 0+a_1+\ldots +a_n$ (left to right)

Accumulators – making factorial tail-recursive

- Two arguments of a pred. forming an **accumulator** pair: the declarative equivalent of the imperative variable (i.e. a variable with a mutable state)
- The two parts: the state of the mutable quantity at pred. entry and exit.
- Example: making factorial tail-recursive. The mid-recursive version:

```
% fact0(N, F): F = N!.
fact0(N, F) :-      (   N =:= 0 ->  F = 1
                    ;   N > 0, N1 is N-1, fact0(N1, F1), F is F1*N
                    ).
| ?- fact0(4, F). ⟹  F = 24 ∼  1*1*2*3*4
```

- Helper predicate: `fact(N, F0, F)`, `F0` is the product accumulated so far.

```
% fact(N, F0, F): F = F0*N!.
fact(N, F0, F) :-  (   N =:= 0 -> F = F0
                    ;   N > 0, F1 is F0*N, N1 is N-1, fact(N1, F1, F)
                    ).
fact(N, F) :-
     fact(N, 1, F).
| ?- fact(4, F). ⟹  F = 24 ∼  1*4*3*2*1
```

Accumulating lists – higher order approaches (ADVANCED)

- Recap predicate `revapp/3`:
  ```
  % revapp(L, R0, R): The reverse of L prepended to R0 gives R.
  revapp0([], R0, R) :-    R = R0.
  revapp0([X|L], R0, R) :- R1 = [X|R0], revapp0(L, R1, R).
  ```
- Introduce the list construction predicate `cons/3`
  ```
  % L1 is a list constructed from the head X and tail L0.
  cons(X, L0, L1) :-       L1 = [X|L0].
  revapp1([], R0, R) :-    R = R0.
  revapp1([X|L], R0, R) :- cons(X, R0, R1), revapp1(L, R1, R).
  ```
- A higher order (HO) solution (in SWI use `foldl` instead of `scanlist`):
  ```
  revapp2(L, R0, R) :-     scanlist(cons, L, R0, R).
  ```
- Summing a list, HO solution (*% sum2(L, Sum): list L sums to Sum.*)
  ```
  plus(X, S0, S1) :-       S1 is S0+X.
  sum2(L, Sum) :-          scanlist(plus, L, 0, Sum).
  ```
- (ADV^2) Appending lists, HO sol. (*% app(L1, L2, L): L1 $\oplus$ L2 = L.*)
  ```
  % decomp(X, C, B): List C can be decomposed to head X and tail B
  decomp(X, C, B) :-       C = [X|B].
  app(A, B, C) :-          scanlist(decomp, A, C, B).
  ```

Accumulating lists – avoiding append

- Example: calculate the list of leaf values of a tree. Without accumulators:

```
% tree_list0(+T, ?L): L is the list of the leaf values of tree T.
tree_list0(leaf(Value), [Value]).
tree_list0(node(Left, Right), L) :-
    tree_list0(Left, L1), tree_list0(Right, L2), append(L1, L2, L).
```

- Building the list of tree leaves using accumulators:

```
tree_list(Tree, L) :-
    tree_list(Tree, [], L). % Initialize the list accumulator to []

% tree_list(+Tree, +L0, L): The list of the
% leaf values of Tree prepended to L0 is L.
tree_list(leaf(Value), L0, L) :- L = [Value|L0].
tree_list(node(Left, Right), L0, L) :-
        tree_list(Right, L0, L1), tree_list(Left, L1, L).

| ?- tree_list(node(node(leaf(a),leaf(b)),leaf(c)), L).  ⟹ L = [a,b,c]? ; no
```

- Note that one of the two recursive calls is tail-recursive.
- Also, there is no need to append the intermediate lists!

Accumulators for implementing imperative (mutable) variables

- Let $L = [x_1, \ldots,]$ be a number list. x_i is *left-visible* in L, iff $\forall j < i.(x_j < x_i)$
- Determine the count of left-visible elements in a list of positive integers:

Imperative, C-like algorithm

```c
int viscnt(list L) {
  int MV = 0; // max visible
  int VC = 0; // visible cnt

loop:
  if (empty(L)) return VC;

  { int H = hd(L), L = tl(L);
    if (H > MV)
      { VC += 1; MV = H; }
    // else VC,MV unchanged
  }
  goto loop;
                }
```

Prolog code

```prolog
% List L has VC left-visible elements.
viscnt(L, VC) :- viscnt(L,
                        0,
                        0, VC).

% viscnt(L, MV, VC0, VC): L has VC-VC0
% left-visible elements which are > MV.
viscnt([], _, VC0, VC) :- VC = VC0.
viscnt(L0, MV0, VC0, VC) :-      % (1)
    L0 = [H|L1],
    (   H > MV0
    ->  VC1 is VC0+1, MV1 = H
    ;   VC1 = VC0, MV1 = MV0     % (2)
    ),
    viscnt(L1, MV1, VC1, VC).    % (3)
```

Mapping a C loop to a Prolog predicate

- Each C variable initialized before the loop and used in it becomes an input argument of the Prolog predicate
- Each C variable assigned to in the loop and used afterwards becomes an output argument of the Prolog predicate
- Each occurrence of a C variable is mapped to a Prolog variable, whenever the variable is assigned, a new Prolog variable is needed, e.g. MV is mapped to MV0, MV1, . . . :
    - The initial values (L0,MV0, . . .) are the args of the clause head[2]   *(1)*
    - If a branch of if-then(-else) changes a variable, while others don't, then the Prolog code of latter branches has to state that the new Prolog variable is equal to the old one,   *(2)*
    - At the end of the loop the Prolog predicate is called with arguments corresponding to the current values of the C variables,   *(3)*

---

Building and decomposing compounds: the *univ* predicate

- BIP =.. /2 (pronounce *univ*) is a standard op. (xfx, 700; just as =, . . .)
- Term =.. List holds if
    - Term = $Fun(A_1, \ldots, A_n)$ and List = $[Fun, A_1, \ldots, A_n]$,
      where Fun is an atom and $A_1, \ldots, A_n$ are arbitrary terms; or
    - Term = C and List = $[C]$, where C is a constant.
      (Constants are viewed as compounds with 0 arguments.)
- Whenever you would like to use a var. as a compound name, use *univ*:
  X = F(A1,...,An) causes syntax error, use X =.. [F,A1,...,An] instead
- Call patterns for *univ*:
    - +Term =.. ?List   decomposes Term
    - –Term =.. +List   constructs Term
- Examples

  | ?- edge(a,b,10) =.. L. $\implies$ L = [edge,a,b,10]
  | ?- Term =.. [edge,a,b,10]. $\implies$ Term = edge(a,b,10)
  | ?- apple =.. L. $\implies$ L = [apple]
  | ?- Term =.. [1234]. $\implies$ Term = 1234
  | ?- Term =.. L. $\implies$ **error**
  | ?- f(a,g(10,20)) =.. L. $\implies$ L = [f,a,g(10,20)]
  | ?- Term =.. [/,X,2+X]. $\implies$ Term = X/(2+X)

An interesting Prolog task

- A job interview question: construct an arithmetic expression containing integers 1, 3, 4, 6 each exactly once, using the four basic arithmetic operators +, -, *, /, 0 or more times, so that the expression evaluates to 24
- Let's write a Prolog program for solving this task:

```prolog
:- use_module(library(lists), [permutation/2]).

% arith_expr(+L, +OpL, +Val, -Expr) :
% Expr is an arithmetic expression containing only operators present
% in the list OpL (operators may be used 0 or more times) and
% integers given in list L (each integer has to appear exactly once),
% so that the value of the expression is Val.
arith_expr(L, OpL, Val, Expr) :-
    permutation(L, PL),              % permute the list of integers into PL
    leaves_ops_expr(PL, OpL, Expr),  % build Expr with PL as the leaves-list
    catch(Expr =:= Val, _, fail).    % check if Expr evaluates to Val, fail
                                     % if there is a division-by-0 error.
```

An interesting Prolog task, cont'd

```
% leaves_ops_expr(+L, +OpL, ?Expr): Expr is an arithmetic expression
% which uses operators from OpL (0 or more times each) whose leaves,
% read left-to-right, form the list L.
leaves_ops_expr(L, _OpL, Expr) :-
    L = [Expr].      % If L is a singleton, Expr is the only element
leaves_ops_expr(L, OpL, Expr) :-
    append(L1, L2, L),            % Split L to nonempty L1 and L2,
    L1 \= [], L2 \= [],
    leaves_ops_expr(L1, OpL, E1),  % generate E1 from L1 (using OpL),
    leaves_ops_expr(L2, OpL, E2),  % generate E2 from L2 (using OpL),
    member(Op, OpL),              % choose an operator Op from OpL,
    Expr =.. [Op,E1,E2].          % build the expression 'E1 Op E2'

| ?- solve(66).
(3*4-1)*6
(4*3-1)*6
6*(3*4-1)
6*(4*3-1)
yes
```

A motivating symbolic processing example

- Polynomial: built from the atom 'x' and numbers using ops '+' and '*'
- Calculate the value of a polynomial for a given substitution of x

```
% value_of(+Poly, +X, ?V): Poly has the value V, for x=X
value_of0(x, X, V) :- V = X.          value_of(x, X, V) :- !, V = X.
value_of0(N, _, V) :-                  value_of(N, _, V) :-
    number(N), V = N.                      number(N), !, V = N.

value_of0(P1+P2, X, V) :-
    value_of0(P1, X, V1),
    value_of0(P2, X, V2),
    V is V1+V2.
value_of0(Poly, X, V) :-               value_of(Poly, X, V) :-
    Poly = *(P1,P2),                       Poly =.. [Func,P1,P2],
    value_of0(P1, X, V1),                  value_of(P1, X, V1),
    value_of0(P2, X, V2),                  value_of(P2, X, V2),
    PolyV = *(V1,V2),                      PolyV =.. [Func,V1,V2],
    V is PolyV.                            V is PolyV.
```

- Predicate value_of works for all binary functions supported by is/2.

```
| ?- value_of(exp(100,min(x,1/x)), 2, V).    ⟹    V = 10.0 ? ; no
```

Building and decomposing compounds: `functor/3`

- `functor(Term, Name, Arity)`:

    `Term` has the name `Name` and arity `Arity`, i.e.
    `Term` has the functor `Name/Arity`.

    (A constant `c` is considered to have the name `c` and arity 0.)

    - Call patterns:

        `functor(+Term, ?Name, ?Arity)` – decompose `Term`
        `functor(-Term, +Name, +Arity)` – construct a most general `Term`   (*)

    - If `Term` is output (*), it is unified with the most general term with the
      given name and arity (with distinct new variables as arguments)

- Examples:

    | ?- functor(edge(a,b,1), F, N).   ⟹   F = edge, N = 3
    | ?- functor(E, edge, 3).   ⟹   E = edge(_A,_B,_C)
    | ?- functor(apple, F, N).   ⟹   F = apple, N = 0
    | ?- functor(Term, 122, 0).   ⟹   Term = 122
    | ?- functor(Term, edge, N).   ⟹   **error**
    | ?- functor(Term, 122, 1).   ⟹   **error**
    | ?- functor([1,2,3], F, N).   ⟹   F = '.', N = 2
    | ?- functor(Term, ., 2).   ⟹   Term = [_A|_B]

Building and decomposing compounds: arg/3

- arg(N, Compound, A): the Nth argument of Compound is A
    - Call pattern: arg(+N, +Compound, ?A), where $N \geq 0$ holds
    - Execution: The Nth argument of Compound is **unified** with A.
      If Compound has less than N arguments, or N = 0, arg/3 fails
    - Arguments are **unified** – arg/3 can also be used for instantiating a
      variable argument of the structure (as in the second example below).
- Examples:
  ```
  | ?- arg(3, edge(a, b, 23), Arg).  ⟹    Arg = 23
  | ?- T=edge(_,_,_), arg(1, T, a),
       arg(2, T, b), arg(3, T, 23).  ⟹    T = edge(a,b,23)
  | ?- arg(1, [1,2,3], A).           ⟹    A = 1
  | ?- arg(2, [1,2,3], B).           ⟹    B = [2,3]
  ```
- Predicate *univ* can be implemented using functor and arg, and vice
  versa, for example:
  ```
  Term =.. [F,A1,A2] ⟺ functor(Term, F, 2), arg(1,
  Term, A1), arg(2, Term, A2)
  ```

Finding arbitrary subterms using `arg/3` and `functor/3`

- Given a term T_0 with a (not necessarily proper) subterm T_n at depth n, the position of T_n within T_0 is described by a *selector* $[I_1,\ldots,I_n]$ ($n \geq 0$):
  ```
  select_subterm(T₀, [I₁,...,Iₙ], Tₙ) :-
          arg(I₁, T₀, T₁), arg(I₂, T₁, T₂), ..., arg(Iₙ, Tₙ₋₁, Tₙ).
  ```
- E.g. within term `a*b+f(1,2,3)/c`, `[1]` selects `a*b`, `[1,2]` selects `b`, `[2,1,3]` selects `3`, `[]` selects the whole term
- Given a term, enumerate all subterms and their *selectors*.

```
% subterm(?T, ?Sub, ?Sel): Sub is subterm in T at position Sel.
subterm(X, X, []).
subterm(X, Sub, [I|Sel]) :-
    compound(X),                % it is important that X is not a var.
    functor(X, _, Arity),       % because functor would raise an error
    between(1, Arity, I),
    arg(I, X, Y), subterm(Y, Sub, Sel).
```

```
| ?- subterm(f(1,[b]), T, S). ⟹   T = f(1,[b]), S = [] ? ;
                              ⟹   T = 1,        S = [1] ? ;
                              ⟹   T = [b],      S = [2] ? ;
                              ⟹   T = b,        S = [2,1] ? ;
                              ⟹   T = [],       S = [2,2] ? ; no
```

Decomposing and building atoms

- `atom_codes(Atom, Cs)`: `Cs` is the list of character codes comprising `Atom`.
  - Call patterns: `atom_codes(+Atom, ?Cs)`
    `atom_codes(-Atom, +Cs)`
  - Execution:
    - If `Cs` is a proper list of character codes then `Atom` is unified with the atom composed of the given characters
    - Otherwise `Atom` has to be an atom, and `Cs` is unified with the list of character codes comprising `Atom`
- Examples:
  ```
  | ?- atom_codes(ab, Cs).          ⟹  Cs = [97,98]
  | ?- atom_codes(ab, [0'a|L]).     ⟹  L = [98]
  | ?- Cs="bc", atom_codes(Atom, Cs). ⟹  Cs = [98,99], Atom = bc³
  | ?- atom_codes(Atom, [0'a|L]).   ⟹  error
  ```

---

[3]A string `"abc..."` is treated as a list of character codes of a, b, ...

Decomposing and building numbers

- `number_codes(Number, Cs)`: `Cs` is the list of character codes of `Number`.
    - Call patterns: `number_codes(+Number, ?Cs)`
                     `number_codes(-Number, +Cs)`
    - Execution:
        - If `Cs` is a proper list of character codes which is a number according to Prolog syntax, then `Number` is unified with the number composed of the given characters
        - Otherwise `Number` has to be a number, and `Cs` is unified with the list of character codes comprising `Number`
- Examples:

    | ?- number_codes(12, Cs). $\implies$ Cs = [49,50]
    | ?- number_codes(0123, [0'1|L]). $\implies$ L = [50,51]
    | ?- number_codes(N, " - 12.0e1"). $\implies$ N = -120.0
    | ?- number_codes(N, "12e1"). $\implies$ **error** (no decimal point)
    | ?- number_codes(120.0, "12e1"). $\implies$ no (The first arg. is given :-)

3. Declarative Programming with Prolog
   - Prolog – first steps
   - Prolog execution models
   - The syntax of the (unsweetened) Prolog language
   - Further control constructs
   - Operators and special terms
   - Working with lists
   - Term ordering
   - Higher order predicates
   - All solutions predicates
   - Efficient programming in Prolog
   - Building and decomposing terms
   - Executable specifications
   - Block declarations
   - Further reading

Executable specifications – what are they?

- An executable specification is a piece of non-recursive Prolog code which is in a one-to-one correspondence with its specification

- Example 1: Finding a contiguous sublist with a given sum

  % sublist_sum(+L, +Sum, ?SubL): SubL is a sublist of L summing to Sum.
  ```
  | ?- sublist_sum([1,2,3], 3, SL). ⟹ SL = [1,2] ? ; SL = [3] ? ; no
  :- use_module(library(lists)). % To import sumlist/2, append/2
  sublist_sum(L, Sum, SubL) :-
      append([_,SubL,_], L),      % SubL is a sublist of L
      sumlist(SubL, Sum).         % Σ SubL = Sum
  ```

- Example 2: Finding elements occurring in pairs

  % paired(+List, ?E, ?I): E is an element of List equal to its
  ```
  % right neighbour, occurring at (zero-based) index I.
  | ?- paired([a,b,b,c,d,d], E, I). ⟹ E = b, I = 1 ? ;
                                    ⟹ E = d, I = 4 ? ; no

  paired(L, E, I) :-
      append(Pref, [E,E|_], L), % L starts with a sublist Pref,
                                % followed by two elements equal to E
      length(Pref, I).          % The length of Pref is I
  ```

3. Declarative Programming with Prolog

Prolog extensions: coroutining (Prolog II)

- Wikipedia: Coroutines are computer program components that allow execution to be suspended and resumed, generalizing subroutines for cooperative multitasking. Coroutines are well-suited for implementing familiar program components such as cooperative tasks, exceptions, event loops, iterators, infinite lists and pipes.
- A typical example of coroutining, the Hamming problem:
  Generate, in increasing order, the sequence of all positive integers divisible by no primes other than 2, 3, 5.
- We implement a simplified version: the only divisors allowed are 2 and 3, using predicates `times/3` and `merge/3` in dataflow programming style
- For this we add the block declaration

  ```
  :- block times(-, ?, ?).
  ```
  Meaning: suspend pred. `times` if the first arg. is an unbound variable
- Also, suspend pred. `merge` if the first or second arg is unbound

  ```
  :- block merge(-, ?, ?), merge(?, -, ?).
  ```

Helper predicates for the Hamming problem

- Multiply each element of a list by a number:

```prolog
% times(As, M, Bs): List Bs is obtained from number list As by
% multiplying each list element by M.
:- block times(-, ?, ?).       % blocks if the 1st arg is a variable.
times([A|X], M, Bs) :-
    B is M*A, Bs = [B|Cs], times(X, M, Cs).
times([], _, []).
```

- Merge two sorted lists into a single sorted list

```prolog
% merge(As, Bs, Cs): Sorted list Cs is obtained by
% collating sorted lists As and Bs, removing duplicates
:- block merge(-, ?, ?), merge(?, -, ?).
merge([A|As], [B|Bs], Cs) :-
    (  A < B -> Cs = [A|Ds], merge(As, [B|Bs], Ds)
    ;  A > B -> Cs = [B|Ds], merge([A|As], Bs, Ds)
    ;           Cs = [A|Ds], merge(As,      Bs, Ds)
    ).
merge([], Bs, Bs).
merge(As, [], As).
```
Solving the Hamming problem via coroutining

```
% U is the list of the first N (2,3)-Hamming numbers
hamming(N, U) :-
    U = [1|_], times(U, 2, X), times(U, 3, Y), merge(X, Y, Z),
    prefix_length([1|Z], U, N).        % A predicate from library(lists)
                    % prefix_length(L, P, N): L has a prefix P of length N
```

Additional slides

Subsequent slides were not presented in the class, these are included as further reading and for reference purposes

Error handling in Prolog

- A BIP for catching exceptions (errors): `catch(:Goal, ?ETerm, :EGoal)`:
- Recall: "`:`" marks a meta argument, i.e. a term which is a goal
- BIP `catch/3` runs `Goal`
    - If no exception is raised (no error occurs) during the execution of `Goal`, `catch` ignores the remaining arguments
    - When an exception occurs, an exception term `E` is produced, which contains the details of the exception
        - If `E` unifies with the 2nd argument of `catch`, `ETerm`, it runs `EGoal`
        - Otherwise `catch` propagates the exception further outwards, giving a chance to surrounding `catch` goals
        - If the user code does not "catch" the exception, it is caught by the top level, displaying the error term in a readable form.

```
| ?- X is Y+1.
! Instantiation error in argument 2 of (is)/2
! goal:  _177 is _183+1
| ?- catch(X is Y+1, E, true).
E = error(instantiation_error,instantiation_error(_A is _B+1,2)) ? ; no
| ?- catch(X is Y+1, _, fail).
no
```

Principles of the SICStus Prolog module system

- Each module should be placed in a separate file
- A module directive should be placed at the beginning of the file:
  - `:- module( ModuleName, [ExportedFunc₁, ExportedFunc₂, ...]).`

- A module directive should be placed at the beginning of the file:
  - :- module(*ModuleName*, [*ExportedFunc₁*, *ExportedFunc₂*, ...]).
- *ExportedFunc_i* – the functor (*Name/Arity*) of an exported predicate
- Example
  - :- module(drawing_lines, [draw/2]).   *% line 1 of file draw.pl*
- Built-in predicates for loading module files:
  - use_module(*FileName*)
  - use_module(*FileName*, [*ImportedFunc₁*, *ImportedFunc₂*, ...])
    - *ImportedFunc_i* – the functor of an imported predicate
    - *FileName* – an atom (with the default file extension .pl);
      or a special compound, such as library(*LibraryName*)
- Examples:
  - :- use_module(draw).   *% load the above module*
  - :- use_module(library(lists), [last/2]). *% only import* last/2
- Goals can be module qualified: *Mod*:*Goal* runs *Goal* in module *Mod*
- Modules do not hide the non-exported predicates, these can be called from outside if the module qualified form is used

Meta predicates and modules

- Predicate arguments in imported predicates may cause problems:

File `module1.pl`:

```
:- module(module1, [double/1]).
% (1)
double(X) :-
        X, X.

p :- write(go).
```

File `module2.pl`:

```
:- module(module2, [q1/0,q2/0,r/0]).
:- use_module(module1).
q1 :- double(module1:p).
q2 :- double(module2:p).
r :-  double(p).              (2)
p :- write(ga).
```

- Load file `module2.pl`, e,g, by `| ?- [module2].`, and run some goals:

```
| ?- q1.   ⟹   gogo
| ?- q2.   ⟹   gaga
| ?- r.    ⟹   gogo                    :-( counter-intuitive
```

- Solution: Tell Prolog that `double` has a meta-arg. by adding at (1) this:

  `:- meta_predicate double(:).`

  This causes (2) to be replaced by '`r :- double(module2:p).`' at load time,
  making predicates `r` and `q2` identical.

Meta predicate declarations, module name expansion

- Syntax of meta predicate declarations
  - `:- meta_predicate ⟨pred. name⟩(⟨modespec₁⟩, ..., ⟨modespecₙ⟩), ... .`
    - ⟨modespec$_i$⟩ can be ':', '+', '-', or '?'.
    - Mode spec ':' indicates that the given argument is a meta-argument
- In all subsequent invocations of the given predicate the given arg. is replaced by its *module name expanded* form, at load time
  - Other mode specs just document modes of non-meta arguments.
- The module name expanded form of a term `Term` is:
  - `Term` itself, if `Term` is of the form `M:X` or it is a variable which occurs in the clause head in a meta argument position; otherwise
  - `SMod:Term`, where `SMod` is the current source module (`user` by default)
- Example, ctd. (`double` is declared a meta predicate in `module1_m`)

  ```
  :- module(module3, [quadruple/1,r/0]).
  :- use_module(module1_m).                        % the loaded form:
  r :- double(p).                        ⟹  r :- double(module3:p).[4]

  :- meta_predicate quadruple(:).
  quadruple(X) :- double(X), double(X).  ⟹  unchanged[4]
  ```

  ---
  [4] The imported goal `double` gets a prefix "`module1:`", not shown here, to save space.
